Repeated oral exposure in drinking water caused a decrease in body weight gain in most studies and resulted in deaths of rats and mice at concentration percents of H_2O_2 greater than 1%. Repeated dosing studies involving oral gavage (injection by stomach tube directly into the stomach) showed progressively more changes of blood parameters at lower concentrations (30–168 mg/kg), decrease of body weight starting at 60 mg/kg, and organ weight changes without histopathology, except for erosion and

scars of mucosa of the stomach, and that only at the highest dose of 506 mg/kg [984, 987].

Although detailed studies that would be needed to fully evaluate the chronic toxicity or carcinogenic potential of H_2O_2 are lacking, several studies showed that long-term oral administration of 0.1–0.15% H_2O_2 caused an inflammatory response in the gastro-duodenal tissue of mice. The response was limited to the glandular stomach and, to a lesser extent, to the peri-pyloric and proximal portion of the duodenum. Some of these lesions may convert into cancerous growths. No inflammatory response was observed in the oral cavity, forestomach, or distal intestinal tract.

The tumorigenicity of hydrogen peroxide (HP) was examined by administering 0.4% hydrogen peroxide solution in drinking water to various strains of mice [988]. In C57BL mice, gastric lesions in the forestomach occurred in over 67% of the mice treated with HP for 120 days, and duodenal lesions were noted in over 80% of the mice that received HP for 60 days. Gastric lesions were found only in the glandular stomach, and duodenal lesions were restricted to the peri-pyloric and proximal part of the duodenum. In mice given 0.4 and 0.1% HP for 420 to 740 days, 5 and 1%, respectively, had duodenal cancer by histological criteria, although they did not show any distant metastasis. In DBA and BALB mice given 0.4% HP for 90 to 210 days, the incidences of gastric lesions reached 30 and 10% at maximum, respectively, and the incidences of duodenal lesions were 60 to 100% and 40 to 69%, respectively.

8.7 Toxicity by Other Means of Hydrogen Peroxide Administration (Animal Tests)

Hydrogen peroxide injection into the bloodstream is an unlikely mode of accidental poisoning, but animal tests were conducted with this mode of administration because much of the H_2O_2 administered by inhalation is decomposed before it reaches the blood stream. Unlikely as it may seem, the literature actually reports one accidental death by accidental injection of dilute hydrogen peroxide into a patient in a hospital. The LD_{50} in rabbits injected intravenously (IV) with 90% H_2O_2 was 0.015 mL/kg body weight. Injections with more dilute H_2O_2 solutions down to 4% H_2O_2 resulted in a smaller LD_{50} , only 0.003 mL/kg body weight. It is assumed that at the higher concentration further distribution of the poison is blocked by immediate gas embolism at the site of injection.

8.7.1 Blood Effects

Erythrocytes separated from blood can degrade gram quantities of H_2O_2 in several minutes. Hemoglobin and similar transition metal porphyrin complexes are good catalysts for H_2O_2 decomposition [989]. During and after IV infusion of 1.0-M H_2O_2 in a 0.9% saline solution for 60 min at a rate of 3×10^{-3} mol H_2O_2 /min, H_2O_2 could not be

detected in dog plasma [990]. Hydrogen peroxide and luminol are used for detection of blood stains in forensic examinations at crime scenes.

8.8 Poisoning Accident Case Histories (Ingestion, Inhalation, and Skin Exposure)

The American Association of Poison Control Centers has tabulated reports of accidental exposure since 1985. Each year, there are several thousands of cases of accidental exposure in the US (including accidental or intentional ingestion) due to consumer use of H_2O_2 as a household topical disinfectant [991]. Fortunately, most of these exposures resulted in no or only minor toxicity symptoms, but fatalities have occurred.

Hydrogen peroxide causes toxicity and symptoms via three main mechanisms: corrosive damage, oxygen gas formation, and lipid peroxidation [992]. Concentrated hydrogen peroxide is an aggressive chemical, and exposure will result in local tissue damage. Ingestion of concentrated (>35%) hydrogen peroxide can result in the generation of substantial volumes of oxygen. Where the amount of oxygen evolved exceeds its maximum solubility in blood, venous or arterial gas embolism may occur, where bubbles prevent the proper flow of blood. The mechanism of central nervous system (CNS) damage is thought to be arterial gas embolism with subsequent brain infarction. Rapid generation of oxygen in closed body cavities can also cause mechanical distension, and there is potential for the rupture of the hollow viscus secondary to oxygen liberation. Intravascular foaming following absorption can seriously impede right ventricular output and produce complete loss of cardiac output. Hydrogen peroxide can also exert a direct cytotoxic effect via lipid peroxidation.

Ingestion of hydrogen peroxide may cause irritation of the gastrointestinal tract with nausea, vomiting, hematemesis, and foaming at the mouth; the foam may obstruct the respiratory tract or result in pulmonary aspiration. Painful gastric distension and belching may be caused by the liberation of large volumes of oxygen in the stomach. Blistering of the mucosae and oropharyngeal burns are common following ingestion of concentrated solutions, and laryngospasm and hemorrhagic gastritis have been reported. Sinus tachycardia, lethargy, confusion, coma, convulsions, stridor, subepiglottic narrowing, apnea, cyanosis, and cardiorespiratory arrest may ensue within minutes of ingestion.

Although most inhalational exposures cause little more than coughing and transient dyspnea, inhalation of highly concentrated solutions of hydrogen peroxide can cause severe irritation and inflammation of mucous membranes, with coughing and dyspnea. Shock, coma, and convulsions may ensue, and pulmonary edema may occur up to 24–72 h post exposure.

A 3-year old girl died following ingestion of an unknown quantity of 40% H_2O_2 solution [993]. Pathological findings at autopsy included edema of the lungs and small erosions of the stomach mucosa, probably due to the lavage tube used to wash out the stomach. The report indicates that the probable cause of death was asphyxia due to

obstruction of the distal respiratory tract by the foam liberated by the peroxide (oxygen gas).

A 6-year old girl died, and her 4-year old friend was in a critical condition with oropharyngeal burns after accidentally ingesting a solution of 35% H_2O_2 [994].

A near-fatality occurred when a 33-year-old woman unintentionally ingested the contents of a 1-pint bottle (<500 mL) of 35% H_2O_2 [995]. The patient was cyanotic and experienced seizures and foaming at the mouth. The abdomen was slightly distended. Neurological signs included the lack of spontaneous eye movement, no verbal response, and withdrawal from noxious stimuli. Laparotomy revealed gas bubbles in the stomach but no perforations. Recovery was complete following treatment.

A child died as a result of oxygen embolism after ingestion of hydrogen peroxide [996]. A total of five similar cases had previously been described. Gastric catabolism of hydrogen peroxide produces oxygen and water. When the amount of oxygen evolved exceeds its maximal blood solubility, venous embolization occurs.

Four unusual cases of caustic injury of the gastrointestinal tract due to hydrogen peroxide occurred in Spain, two cases due to oral ingestion, and another two due to the accidental administration of enemas containing hydrogen peroxide [997].

Then there is the case of a 39-year-old man who inadvertently ingested 250 mL of unlabeled 35% hydrogen peroxide [998]. The hydrogen peroxide was in an unlabeled container in a friend's refrigerator and was mistaken for water. Immediately after ingesting the hydrogen peroxide, he realized it was a caustic substance and drank 500 mL of water to induce vomiting. He experienced mild epigastric pain without shortness of breath or oropharyngitis. On arrival at the emergency department, he was hemodynamically stable and in no respiratory distress. The oral cavity and oropharynx were slightly erythematous, and the abdominal examination revealed mild epigastric tenderness but no distension, and normal bowel sounds. Esophagogastroduodenoscopy revealed a normal oral cavity and normal esophagus, but the stomach had suffered grade 2 diffuse caustic mucosal injury of the entire stomach, including the cardia, characterized by superficial erosions with exudates and edema.

Accidental ingestion of industrial-strength H_2O_2 is very rare. Fatal outcomes have been reported with 35% H_2O_2 solutions. There is the case of a 6-year-old boy who unintentionally ingested an unknown quantity of 60% hydrogen peroxide [999]. Upon admission to a pediatric intensive care unit he was intubated and received ventilatory assistance for 48 h. Upper gastrointestinal endoscopy was performed soon after admission, and laparoscopy was performed 24 h later. Recovery was satisfactory, and the patient was discharged on day 18 with no evidence of lasting pathological damage.

Hydrogen peroxide is used as a disinfectant during pasteurization of milk prior to cheese making where it is sometimes improperly stored in commercial drink containers without adequate labeling. Three cases of accidental ingestion of 60% H_2O_2 were reported in the milk industry in Spain [1000]. The patients were male stockbreeders aged 30, 45, and 62 years, respectively. After accidental ingestion, one of them was

admitted comatose and required assisted ventilation. After recovering consciousness, migratory paresis of the right limbs and of the cranial nerve were observed, which were reversed after 10 days, but a left hemiparesis persisted for 2 months. Upper gastrointestinal tract lesions, particularly in the stomach, were detected in all cases. The outcome was satisfactory in the three patients, with complete remission of the lesions within a few months.

Ingestion of a small amount of concentrated hydrogen peroxide can cause cerebral air gas embolism (CAGE). A 48-year-old male took two sips of 33% H_2O_2 [1001]. A short time later, he developed hematemesis, left-sided hemiplegia, confusion, and left homonymous hemianopsia. Diagnostics indicated ischemia due to CAGE. Hyperbaric oxygen therapy (HBOT) is the standard of care in the treatment of CAGE. The patient underwent HBOT at 3 atm absolute (ATA) for 30 min and 2.5 ATA for 60 min, 18 h after arrival, resulting in reversal of both the clinical and radiologic abnormalities.

Arterial gas embolization in the central nervous system is a relatively rare complication. There are three possible mechanisms of gas embolization: persisting patent foramen ovale, pulmonary gas emboli caused by aspiration of H_2O_2 to the lower respiratory tract, and formation of gas embolism after it reaches the brain. There is the case of a 54-year-old woman with brain gas embolism after accidental ingestion of concentrated H_2O_2 [1002].

A rocket test stand worker who inadvertently inhaled vapors from 90% H_2O_2 suffered increased salivation and a scratchy throat and developed a non-purulent inflammation of the upper respiratory tract.

8.9 Therapy of Hydrogen Peroxide Poisonings

Gut decontamination is not indicated following ingestion, due to the rapid decomposition of hydrogen peroxide by catalase to oxygen and water. If gastric distension is painful, a gastric tube should be passed to release gas. Early aggressive airway management is critical in patients who have ingested concentrated hydrogen peroxide, as respiratory failure and arrest appear to be the proximate cause of death. Endotracheal intubation, or rarely, tracheostomy may be required for life-threatening laryngeal edema. Contaminated skin should be washed with copious amounts of water. Skin lesions should be treated as thermal burns; surgery may be required for deep burns. In the case of eye exposure, the affected eye(s) should be irrigated immediately and thoroughly with water or 0.9% saline for at least 10–15 min. Instillation of a local anesthetic may reduce discomfort and assist more thorough decontamination.

Ingestion of concentrated H_2O_2 has been associated with venous and arterial gas embolic events, hemorrhagic gastritis, gastrointestinal bleeding, shock, and death. Although H_2O_2 is generally considered a benign ingestion poison in low concentrations, case reports have described serious toxicity following high-concentration ex-

posures. Hyperbaric oxygen (HBO) has been used with success in managing patients suffering from gas embolism with and without manifestations of ischemia. A case history identified 11 cases of portal gas embolism with victims' ages ranging from 4 to 89 years [1003]. In ten cases, 35% H_2O_2 was ingested, and in one case, 12% H_2O_2 was ingested. All abdominal computed tomography (CT) scans demonstrated portal venous gas embolism. Hyperbaric treatment was successful in completely resolving all portal venous gas bubbles in nine patients and nearly resolving them in two others. Ten patients were able to be discharged home within 1 day, and one patient had a 3.5-day length of stay.

Intragastric administration of 6% H_2O_2 induced gastric mucosal hemorrhagic lesions in rats. Intraperitoneal administration of rebamipide, an amino acid derivative of 2-(1H)-quinolinone, an anti-ulcer medication, at 10 to 100 mg/kg dose-dependently prevented the H_2O_2 -induced mucosal lesions [1004].

8.10 Mutagenicity of Hydrogen Peroxide

Hydrogen peroxide can induce mutations. Hydrogen peroxide was investigated for its potential to induce gene mutations in V79 Chinese hamster cells [1005]. Exposure of $2\text{--}3 \times 10^6$ cells/100-mm dish to 0.5–4.0 mM H_2O_2 for 1 h resulted in a concentration-dependent increase in the frequency of 6-thioguanine-resistant clones. At 4 mM H_2O_2 the mutation frequency was increased about sixfold above that in controls, and survival of the cells was reduced by 50%. Cytotoxicity was markedly increased at lower cell densities. The results showed that mutagenicity of H_2O_2 in mammalian cells in vitro previously escaped attention because the concentrations tested were too low, presumably because the likely toxicity of H_2O_2 to V79 cells treated at high cell densities was overestimated.

In bioassays conducted under controlled, comparable conditions, weak direct mutagenicity responses were observed for hydrogen peroxide in the standard (Ames test) agar plate incorporation bioassay with *Salmonella typhimurium* strains TA97, TA98, TA102, and TA1537, in a 20-min preincubation test with strains TA97, TA98, TA100, TA102, TA1537, and TA1538, and in a liquid incubation modification using strain TA1537 [1006]. These results conclusively demonstrated that hydrogen peroxide is a weak mutagen, especially in strains that are sensitive to oxidative damage under suitable bioassay conditions.

Hydrogen peroxide is genotoxic to bacteria as tested in the standard Ames test. Hydrogen peroxide is also genotoxic to mammalian cells in culture, inducing sister chromatid exchange, deoxyribonucleic acid (DNA) single-strand breaks (gene mutations), chromosomal aberrations, micronuclei, unscheduled DNA synthesis, and transformation. However, the genotoxic potential of hydrogen peroxide is dependent upon direct contact with genetic material. Direct contact of cells with hydrogen peroxide is usually only at the site of initial contact during whole-body exposure, while cells in culture are

all uniformly exposed without the benefit of the body's ability to metabolize hydrogen peroxide [985].

Hydrogen peroxide had a mutagenic effect on fungi and bacteria (e.g., Ames test), but not on insects or mammalian cells in vitro. Chromosome aberrations (mainly chromatid breaks or micronuclei) were induced in V79 cells, Chinese hamster cells, human embryonic fibroblasts, human leucocytes, Syrian hamster, and Balb/c mouse cells after in vitro treatment with H_2O_2 . H_2O_2 induced DNA-repair in *Escherichia coli*, *Salmonella typhimurium* in the presence of metabolic activation, catalase, or superoxide dismutase (SOD); no effect was observed in the DNA-repair test or the SOs chromotest using *E. coli* strains. H_2O_2 induced DNA single-strand breaks in bovine lens epithelial cells, rat intestinal epithelial cells, leukemia cells, rat hepatocytes, human lymphocytes, and human bronchial epithelial cells [985].

Oxidative DNA damage caused by hydrogen peroxide was enhanced by copper zinc superoxide dismutase (CuZnSOD) in a concentration-dependent manner, as reflected by the formation of 8-hydroxy-2'-deoxyguanosine (8-OH-dG) and strand breaks [1007]. The effects of CuZnSOD on hydrogen peroxide-induced DNA damage and mutation was attributed to reactive oxygen species, probably hydroxyl-free radicals, formed predominantly by the reaction of hydrogen peroxide and free Cu^{2+} released from oxidatively damaged CuZnSOD.

8.11 Carcinogenicity of Hydrogen Peroxide

The suspected carcinogenicity of hydrogen peroxide has been thoroughly examined in animal tests and actively disputed in the scientific literature, but it has not been classified as a known human carcinogen.

Hydrogen peroxide increased duodenal and upper jejunal carcinogenesis in rats [1008]. A drinking water study in a catalase-deficient mice strain reported the observation of dose-related hyperplasia (at a high incidence) and localized carcinomas (at a low frequency) in the duodenum of the animals [1009–1011]. A solution of 0.4% H_2O_2 was given to the mice as drinking water for about 6 months [1012]. Incidences of duodenal tumor induced by oral administration of hydrogen peroxide (HPO) and catalase activities in the duodenal mucosa, blood, and liver were correlated in four different strains of mice. The results indicated that the incidence of duodenal tumor induction by H_2O_2 is dependent on the individual mouse strain and may be determined by the genes controlling the catalase activities.

These publications triggered a violent scientific debate on the possible carcinogenic potential of hydrogen peroxide and its relevance to humans, and some of its findings have been furiously disputed. A historical and very detailed account of these disputes is given in [969].

According to the Japanese authors all lesions, including tumors, regressed after cessation of the administration of hydrogen peroxide. This finding caused some

doubts on the nature of the observations reported. It appears that the control incidence was lower than other published values in this mouse strain. A subsequent study with different strains of mice showed that there was a strong negative correlation between the incidence of duodenal tumors (hyperplasia or neoplasia) and catalase activities in duodenal mucosa, blood, and the liver [1012]. In a comparable study with rats, drinking water administration of hydrogen peroxide seemed not to be associated with the occurrence of tumors, and there were no tumors in the gastrointestinal tract at all. Studies investigating a possible tumor initiating or promoting activity of hydrogen peroxide consistently showed that hydrogen peroxide is not a tumor initiator and showed contradictory results regarding tumor promotion (promotion or even inhibition of tumors was observed). Under certain conditions a weakly tumor promoting activity cannot be excluded and is likely related to chronic inflammation at continuous exposure. The fact that mammalian cells have built-in defenses against reactive oxygen species arising in endogenous metabolism further reduces the significance of the findings of Ito. Taken together the available data lead to the conclusion that the carcinogenicity of hydrogen peroxide reported in catalase-deficient mice strains is not relevant for humans.

When diluted hydrogen peroxide was given orally to rats, no significant differences in cancer frequency occurred between the two test groups and the control group. No evidence of tumor formation was found 1 year after exposure of mouse skin to 5 mass-% hydrogen peroxide, but benzoyl peroxide was a carcinogen [1013]; see also [1014] and [1015].

A study of the effects of twice weekly topical applications of hydrogen peroxide on the buccal epithelium of Syrian hamsters showed that hydrogen peroxide can, by itself, induce pathologic changes frequently associated with preneoplastic lesions; it may also augment carcinogenesis associated with known carcinogens like 9,10-dimethyl-1,2-benzanthracene [1016]. In animals treated with 30% H_2O_2 alone, histopathologic examination after 22 weeks revealed hyperkeratosis and hyperplasia in all animals with hyperchromatic cells and mild dysplasia in four of nine; no tumors were seen. The DNA damage caused by hydrogen peroxide is enhanced in the presence of trace metals [1017].

Concern regarding carcinogenicity of hydrogen peroxide arises from its ability to act as a strong oxidizing agent in the metabolism and cell division. In short-term genotoxicity tests, H_2O_2 has given predominantly positive results. However, these assays were performed using either bacterial strains engineered to be exquisitely sensitive to oxidant damage or mammalian cells deficient in antioxidant enzymes. Significantly, the addition of antioxidant protective measures (normally present *in vivo*) to these assay systems would protect against H_2O_2 genotoxicity. In most whole animal studies, H_2O_2 exposure neither initiated nor promoted tumors. In mice, however, 0.4% H_2O_2 in drinking water was reported to induce hyperplastic lesions of the duodenum and to erode areas in the glandular stomach epithelium. Owing to the chemistry of dilute H_2O_2 solutions and the anatomy/physiology of the gastrointestinal tract, it is

unlikely that orally ingested H_2O_2 reaches the duodenum. Instead, greatly decreased water consumption and the subsequent mechanical abrasion of the luminal lining on ingestion of pelleted dry rodent chow is the most likely cause of the observed gastric and duodenal lesions following H_2O_2 administration in drinking water. Significantly, when hamsters received high doses of H_2O_2 by gastric intubation (and water intake was not affected), the gastric and duodenal epithelia appeared normal. In-depth analysis of the available data supported the conclusion that oral ingestion of H_2O_2 should not be considered a carcinogenic threat [1018].

8.12 Teratogenicity of Hydrogen Peroxide

So far, no problems associated with reproduction in animals as the result of exposure to hydrogen peroxide have been found [1014].

8.12.1 Genotoxicity of Hydrogen Peroxide

The genotoxicity of H_2O_2 has been studied extensively [969]. This paper by Jacobi has a very good list of references on toxicity, and the following information was copied from that source. Hydrogen peroxide can react directly with isolated deoxyribonucleic acid (DNA) forming hydroxylated DNA bases. In *in vitro* tests, without metabolic activation, H_2O_2 induced gene mutations, primary DNA damage, chromosome aberrations, and micronuclei in mammalian cells, as well as morphological cell transformations. Addition of enzymes like catalase, however reduced or abolished the genotoxic response [1019]. The CEFIC Peroxygen Sector group performed several experiments on animals in order to study the genotoxic potential in mammals *in vivo*. In these studies, efforts were made to maximize exposure of the potential target organs; no chromosomal aberrations or micronuclei were observed in the bone marrow of rats and catalase deficient mice after repeated oral or single intraperitoneal administration. After intravenous administration in rats at the maximal tolerated dose, no unscheduled DNA synthesis was observed in the liver, although such an effect was observed in the rat's liver cells exposed *in vitro* to hydrogen peroxide. In a study of local genotoxicity to mouse skin, 70% hydrogen peroxide did not cause any mutations, hydroxylation of DNA bases, or give an indication of cellular proliferation, thus suggesting that the substance has no local genotoxic potential *in vivo*. In mechanistic studies, it was recently shown that hydrogen peroxide induced controlled cell death (apoptosis) rather than genotoxic lesions in cell cultures of human lymphocytes and did not induce 8-hydroxy-guanosin formation.

8.13 Bacterial Toxicity of Hydrogen Peroxide

The widespread use of hydrogen peroxide as a clean, non-residue disinfectant is based on its ability to kill harmful bacteria, including those causing bad odor from the mouth. Hydrogen peroxide vapor is used in a method like ethylene oxide or ultraviolet light to prevent bacterial contamination during packaging and sealing of sterile surgical supplies and dispensing of IV solutions. Like ethylene oxide, hydrogen peroxide vapor in these industrial settings is an explosion hazard.

The question of the survivability of tough strains of bacteria immersed in varying concentrations of H_2O_2 in water surfaced again during the search for extraterrestrial life. All kinds of life forms have been subjected to simulated conditions like they might exist on Europa or Ganymede.

Hydrogen peroxide concentrations that are not strong enough to kill the bacteria outright may cause unwanted mutations in the survivors [1020]. Externally applied hydrogen peroxide rapidly permeates the bacterial cell and causes at least two classes of potentially lethal damage: Mode one killing appears to be due to DNA damage, has a maximum near 1 to 3 mM H_2O_2 , and requires active metabolism during exposure. Mode two killing is due to uncharacterized damage, occurs in the absence of metabolism, and exhibits a classical multiple-order dose-response curve up to at least 50 mM H_2O_2 . Scavenging enzymes, such as catalase and superoxide dismutase, contribute to resisting oxidative stress [1021].

Hydrogen peroxide has been recommended for cleanup of spilled industrial pollutants in the soil. Under conditions harsh enough to destroy persistent chemicals like trichloroethylene, all bacterial life in the soil would be destroyed also. On the other hand, at lower concentrations, hydrogen peroxide may provide the oxygen that the bacteria need to chew up petroleum products and other nasty chemicals.

Hydrogen peroxide vapor has been evaluated for the external sterilization of spacecraft (before they are sent to other planets) to prevent contamination of extraterrestrial habitats by terrestrial bacteria. So, if HTP is not storable enough to be on the inside of spacecraft sent to other planets, it may at least be useful to sterilize the outside [1022]. Ethylene oxide/fluorocarbon mixtures used to be used for spacecraft sterilization at JPL, but these mixtures stratify if left sitting undisturbed without additional forced convection.

8.14 Occupational Exposure Limits

The accepted occupational exposure limit for H_2O_2 as an 8-h time weighted average (TWA) is 0.14 mg/m³ or 0.1 ppm [973]. The NIOSH REL TWA is 1 ppm (1.4 mg/m³) and the OSHA PEL TWA is 1 ppm (1.4 mg/m³). Short-term exposure limits (STEL, in mg/m³) range from 2.8–4.2 mg/m³ (5–15 min). In the United Kingdom (UK) the STEL is 3 mg/m³ (for 10 min) while the United States (US) does not have an accepted STEL

value. A ceiling is accepted by some countries with a range of 1–2 mg/m³. Neither the UK nor the US have a ceiling value. The maximum concentration from which one could safely escape within 30 min without a respirator has been estimated to be 75 ppm. This concentration is thought not to cause any impairment or irreversible health effects immediately dangerous to life or health (IDLH). The National Institute for Occupational Safety and Health (NIOSH) set an Immediately Dangerous to Life and Health standard (IDLH) of 75 ppm [1023–1025]. That is of the same order of magnitude as hydrazine, although the IDLH of hydrazine was lowered from 80 ppm to 50 ppm in 1995 while the IDLH for H₂O₂ remained unchanged at 75 ppm; see also [1026].

8.15 Epidemiological Studies of Occupational Exposure

In a health surveillance survey of Degussa production staff done at five sites (Europe and USA) they evaluated 110 people, 80 of those had worked there for >10 years (some for a maximum 40 years), and none of the personnel showed any impairment of lung function or other adverse health effects [102].

An industrial hygiene survey was conducted at NASA Stennis Space Center to evaluate personal and area airborne exposure levels to hydrogen peroxide during experimental engine testing [1027]. Survey data were collected during a 3-week period in 1999 for typical operations like obtaining HTP bulk samples for analysis, transfer to oxidizer run tanks (**NOT fuel tank** – as written by Brever) and engine testing. Personal sample results were well below the permissible exposure limit (PEL) of 1 ppm. However, the results of area samples during testing indicated significant short-term elevations above the PEL. Administrative controls such as observation of wind direction and post-test wait time employed were enough to control personal exposures to hydrogen peroxide vapors and should be continued during future testing operations. Personal protective equipment used, such as natural rubber gloves, boots and suits, face shields, goggles, and hard hats, was adequate to protect personnel from potential skin contact with spilled HTP liquid.

8.16 Environmental Fate of Hydrogen Peroxide

A good summary of the environmental fate of hydrogen peroxide was given in the paper by Jacobi [969].

8.16.1 Environmental Fate of Hydrogen Peroxide in the Atmosphere

Natural H₂O₂ concentrations in the atmosphere vary with temperature, solar radiation intensity, humidity, and the presence of scavengers (CH₄, CO, volatile organic

compounds) and inhibitors (SO_2 , NO_2). H_2O_2 emissions to the environment from industrial and domestic sources have little effect due to their rapid decomposition in the wastewater. The amount of H_2O_2 deposited by rainwater into surface waters is greater than that from industrial and domestic sources together.

The atmospheric fate of hydrogen peroxide is governed by simultaneous generation and degradation reactions resulting in a stationary equilibrium [1028]. The formation of atmospheric hydrogen peroxide is photochemically mediated. Consequently, natural concentrations are latitude, altitude, seasonal, and diurnal cycle-dependent and are different in the proximity of industrial pollutants and in a clean atmosphere away from civilization. High solar irradiation leads to high hydrogen peroxide concentrations. Hydrogen peroxide in the atmosphere is produced through free radical reactions. Light, oxygen, hydrocarbons, and free radicals in the atmosphere favor hydrogen peroxide formation. In unpolluted atmospheres, the formation of H_2O_2 is ultimately due to the photolysis of ozone at wavelengths $< 310\text{ nm}$ to give oxygen atoms, which then react with water vapor. About twice as much H_2O_2 is formed at 100% relative humidity than at 50% humidity at ambient temperature.

8.16.2 Environmental Fate of Hydrogen Peroxide in Surface Waters

Hydrogen peroxide has been evaluated as a herbicide for aquatic weeds or algae because it will not leave residues or accumulate in the food chain like other herbicides [1029]. An excellent review with 289 references covers the role of H_2O_2 in natural waters, including determination methods, distribution of H_2O_2 , formation of H_2O_2 in natural waters, H_2O_2 and the redox system, decomposition of H_2O_2 , and natural purification processes in natural waters [1030]. Chemical and biochemical processes defining the H_2O_2 cycle in natural waters and in biological objects were examined. Assessments were given of the inflow of H_2O_2 into surface waters from the atmosphere, and data were collated on the H_2O_2 content of seawater and freshwater. Photochemical, catalytic, and biochemical processes make the main contribution to H_2O_2 formation. The interaction between intracellular redox processes of aquatic microorganisms and the redox state of aquatic media determines the surviving equilibrium concentration. Biotic and abiotic processes for the decomposition of H_2O_2 in natural waters and free radicals connected with the H_2O_2 cycle in the self-purification of natural aquatic media consume and generate H_2O_2 .

The main course of degradation of hydrogen peroxide in natural waters is the degradation by biological material, e.g., plankton and algae. The half-life in water decreases with increasing size of the microbial population in water. Consequently, the half-life of spilled H_2O_2 in natural waters can range from a few hours to several days. Degradation is also catalyzed inorganically by transition metal ions. Direct photolysis does not play a major role in aquatic decomposition.

Seawater contains enough copper and iron ions to catalyze the swift decomposition of hydrogen peroxide just as fast as it forms during sunlight illumination [1031].

8.16.3 Environmental Fate of Hydrogen Peroxide in Wastewater

In municipal wastewater, hydrogen peroxide degrades rapidly because of the content of microorganisms and organic material. Half-lives were reported to be below 15 min or even below 2 min. Hydrogen peroxide is used routinely in the deodorization of wastewater in water treatment plants.

8.17 Aquatic Toxicity of Hydrogen Peroxide

At concentrations <200 mg/L in wastewater, H_2O_2 does not affect the performance of biological wastewater treatment works (activated sludge process). It is quickly degraded and has even been shown to stimulate biodegradation in wastewater treatment works. At higher concentrations (>200 mg/L) H_2O_2 becomes toxic to microorganisms.

Hydrogen peroxide is used to sterilize holding pens in aquaculture farms and, therefore, has the potential to be released from aquaculture facilities when the pens are flushed before a new generation of fish is planted. The release of rinse waters would pose a risk to aquatic invertebrates. A flowthrough, continuous exposure test system was developed to expose *Daphnia magna* to hydrogen peroxide for 21 days [1032]. Hydrogen peroxide concentrations ≤ 1.25 mg/L had no significant effect on *Daphnia* time to death compared to controls and no significant effect on the time to first brood production and the number of broods produced. Concentrations ≤ 0.63 mg/L had no significant effect on the total number of young produced. Concentrations ≥ 0.32 mg/L had a negative effect on *Daphnia* growth.

The 96-h LC50 values for freshwater fish range from 16.4 to 37.4 mg/L H_2O_2 . The 48-h EC50 value for *Daphnia pulex* was 2.4 mg/L and the 24-h EC50 for *Daphnia magna* was 2.3 mg/L. The toxicity of hydrogen peroxide to different species of fish is summarized in Table 65.

Table 65: Hydrogen peroxide toxicity to fish.

Species	Latin name	Effect	Concentration $\mu\text{g/L}$
Rainbow trout, fingerling	<i>Salmo gairdneri</i>	Lethality, 48 h	>40
Squawfish	<i>Ptychocheilus oregonensis</i>	No mortality, LCo, 24 h	10
Channel catfish	<i>Ictalurus punctatus</i>	LCA, 96 h	37.4
Guppy	<i>Lebistes reticulatus</i>	Unharmd	34
Fathead minnow	<i>Pimephales promelas</i>	LC ₅₀ , 96 h	16.4

See secondary source, ECETOC [985] for the original source of data.

When assessing the risk of hydrogen peroxide to environmental organisms, the background concentrations in the environment and the capacity of life forms to adapt to increased hydrogen peroxide concentrations must be considered.

9 Explosion Hazards of Hydrogen Peroxide

Hydrogen peroxide can explode in the liquid and in the vapor state. The explosive tendencies of liquid hydrogen peroxide depend on the intensity of the energetic stimulus. Pure 98% H_2O_2 could not be made to explode in the drop weight test or in the bullet impact test. Hydrogen peroxide becomes much more sensitive and more likely to explode in the presence of organic contaminants.

9.1 Drop Weight Impact Sensitivity of Hydrogen Peroxide

Liquid HTP in any concentration between 90 and 99% H_2O_2 could not be made to explode in any of the drop weight impact testers, even in the presence of a gas bubble on top of the liquid.

Drop weight tests are not always very reproducible. More accurate shock impact sensitivity tests can be carried out if the impactor is accelerated not by gravity, but in a compressed gas gun.

A gas-driven two-stage gun was used to produce well-defined shock inputs to understand and quantify the initiation and detonation properties of highly concentrated H_2O_2 [1033, 1034]. Multiple magnetic gauges were used to make *in-situ* measurements of the growth of reaction and subsequent detonation in the liquid. These experiments were designed to be one-dimensional to eliminate any difficulties that might be encountered with large critical diameters. Several experiments were completed on ~98 mass-% $\text{H}_2\text{O}_2/\text{H}_2\text{O}$ mixtures where initiation was observed in some experiments showing homogeneous shock initiation behavior. The initial mechanical shock pressurizes and heats the mixture. After an induction time, a thermal explosion type reaction produces an evolving reactive wave that strengthens and eventually overdrives the first wave, producing a detonation. From such measurements, unreacted H_2O_2 Hugoniot information, times (distances) to detonation (Pop-plot points) that indicate low sensitivity and detonation velocities of high concentration $\text{H}_2\text{O}_2/\text{H}_2\text{O}$ solutions were obtained that agreed with earlier estimates.

9.2 Bullet Impact Sensitivity of Hydrogen Peroxide

Unalloyed titanium, Ti-6Al-4V, Ti-25Zr, and the Ti-19W-11Cr-3Al all-beta alloy have been shown to be impact sensitive in 90% hydrogen peroxide. Impact energies re-

quired to initiate the reaction, however, were considerably higher than those required for LOX. The black oxide films formed on some alloys with long exposures to 90% H_2O_2 did not exhibit pyrophoric properties when scratched or impacted [1035].

9.3 Cap Sensitivity of Liquid Hydrogen Peroxide

Cap sensitivity tests using No. 6 or No. 8 blasting caps were negative. In another test, a 75-L sample of 99.8% H_2O_2 was shocked with a 15-g dynamite booster and did not explode [934]. Only the barrel in which the test was conducted ruptured from the hydraulic shock.

Pure 100% H_2O_2 can only be detonated in sturdy containers with rigid confinement [1036]. It was claimed that aqueous solutions of less than 94% H_2O_2 will decompose explosively if catalyzed but will not detonate.

The following information is quoted only from a second-hand source because the original report [1037] was not available. The test data indicated that detonations in 99% hydrogen peroxide decreased considerably with distance from the booster, and that detonation speeds decreased with decreasing tube diameter. At diameters of less than 1 in., the detonation was quenched inside the tube; 99% HTP tested in a 1-in. ID, 3/16-in. wall CRES tube with a 20-g tetryl booster showed detonation speeds starting at 7060 m/s decreasing to 4715 m/s with an average of 5590 m/s measured across a distance of 1 m. In a similar test with 99% HTP in a 1-in. ID, 3/16-in. wall CRES tube 10-g tetryl booster there was no explosion. The same negative results were obtained with 90% HTP in a 1-in. ID, 3/16 in. wall CRES tube using 20 g tetryl as the booster charge.

The detonation velocity of an 86/14 mass-% $\text{H}_2\text{O}_2/\text{H}_2\text{O}$ mixture was estimated as ca. 6000 m/s (measured using a streak camera). The initial shot temperature and the tube diameter were not specified, but the confining tube material was listed as steel [1038].

The following information is quoted only from a second-hand source because the original report was not available. With both 90 and 99.5% H_2O_2 at 344 K (160 °F), 15 g of #15 Hercomite™ dynamite initiated in the center of 113 kg (250 lb_m) of propellant contained in a metal drum caused only minor damage to drum [1039]. With 98% HTP, a detonation could be initiated in a 1.5-in. schedule 80 CRES pipe by rapid compression, but detonation did not propagate into a 250-lb drum. With 99% HTP, a detonation could be initiated in a 1-in. ID, 0.18 in. wall CRES pipe. The 1-in. pipe was connected to a narrower, 0.5-in. ID, 0.035 in. wall CRES pipe, also filled with 99% HTP. The detonation did not propagate into the 0.5-in. pipe.

The US Bureau of Mines determined the critical diameters of liquid 86.0/14.0 and 90.7/9.3 mass-% $\text{H}_2\text{O}_2/\text{H}_2\text{O}$ mixtures confined in Al-61STS tubes with IDs of 26.7, 31.8, and 40.9 mm and at initial temperatures between 298 and 343 K (25 and 70 °C) [1040]. At 323 K (50 °C) or higher 86% H_2O_2 contained in 1.61 in. ID Al tubes, will detonate at 5600 mm/s when initiated by a strong booster, but not at smaller diameters. For the

86% material, the critical diameter was ca. 40.6 mm at 323 K (50 °C) and 35.6 mm at 343 K (70 °C) and, for the 90.7% material, the critical diameter decreased from 40.6 mm at 298 K (25 °C) to 20.3 mm at 343 K (70 °C). Rough detonation speed measurements gave speeds in the range of 5500–6000 m/s. The gap over which the 90.7% solution will propagate detonation increased with increasing temperature.

The *Fedoroff Encyclopedia of Explosives and Related Items* contains a good summary of the explosive properties of hydrogen peroxide and its mixtures [1041].

Hydrogen peroxide is an unusual explosive as it contains only hydrogen and oxygen. This makes spectroscopic studies of shock-induced reactions and decomposition of the molecule simpler than those for conventional nitrogen-containing explosives. UV/visible emission spectroscopy was used to follow the buildup of detonative reaction in pure hydrogen peroxide [1042]. Spectra were captured on a nanosecond timescale, and the data supported the proposed shock-induced reaction pathway. This was then compared to the reaction scheme found for hydrogen peroxide decomposition at room temperature and pressure.

The failure diameter and detonation speed for 90.5 mass-% H_2O_2 confined in thick seamless 304 stainless steel tubing and fired at ca. 303 K (30 °C) was measured [225]. The geometry of the sample holder tube was as follows: ID 45.47 mm, OD 50.88 mm, and length 610 mm. The measured density of the H_2O_2 sample was $1.390 \pm 0.002 \text{ g/cm}^3$ at 297.4 K (24.3 °C); this corresponds to 90.5 mass-% H_2O_2 . The shots were strongly boosted with SE-1 detonators, PBX-9407 pellets, and a piece of PBX-9404 of 51 mm diameter and 44 mm high. The detonation speed and knowledge of the diameter effect curves of other liquid explosives were then used to estimate the infinite-medium (i.e., plane wave) detonation speed of this material. Ambient condition sound velocity measurements and the universal liquid Hugoniot form were used to obtain the unreacted Hugoniot of the 90.5/9.5 mass-% $\text{H}_2\text{O}_2/\text{H}_2\text{O}$ mixture. This Hugoniot and the Rayleigh line obtained from the estimated infinite medium detonation wave speed were used to predict the von Neumann spike pressure of the material. Estimates of the fully reacted (i.e., products) Hugoniot, the C-J detonation pressure, and the C-J detonation speed for other $\text{H}_2\text{O}_2/\text{H}_2\text{O}$ mixtures were obtained using the CHEETAH equilibrium thermochemical code. In Figure 59, the lower points are the calculated C-J detonation speeds for $\text{H}_2\text{O}_2/\text{H}_2\text{O}$ mixtures at an initial temperature of 296 K (23 °C), as obtained with the CHEETAH code using the Becker-Kistiakowsky-Wilson (BKW) product library. A general analytical expression is given for the corrected primary shock Hugoniot of any $\text{H}_2\text{O}_2/\text{H}_2\text{O}$ mixture at 295.7 K (22.6 °C). A least squares fit line has been drawn through the data points. The solid line corresponds to the equation

$$v_{\text{D CJ}} = 2.019 + 0.0412 \times C_{\text{H}_2\text{O}_2}$$

where $v_{\text{D CJ}}$ is the detonation velocity in km/s, and $C_{\text{H}_2\text{O}_2}$ is the hydrogen peroxide concentration in mass-%. The dashed line corresponds to the equation

$$v_{\text{D CJ}} = 2.56 + 0.0412 \times C_{\text{H}_2\text{O}_2}$$

Figure 59: Calculated and measured C-J detonation speeds for $\text{H}_2\text{O}_2/\text{H}_2\text{O}$ mixtures at an initial temperature of 296 K (23 °C). (Reprinted and modified from [225], with permission from © 2000 American Chemical Society; permission conveyed through RightsLink.)

where v_{DCJ} is the detonation velocity in km/s, and $C_{\text{H}_2\text{O}_2}$ is the hydrogen peroxide concentration in mass-%. The lonely square data point on the dashed line is the measured detonation velocity of 6.294 km/s (after applying temperature and infinite diameter corrections). The dashed line through the experimental point is a translation (holding the slope constant) of the lower line, providing an estimate of the expected detonation speed as a function of chemical composition. The (corrected) experimental detonation speed is 9% higher than the CHEETAH calculation of 5.75 km/s, which is a rather large difference.

Extrapolating from 90.5% H_2O_2 to 100% H_2O_2 , neat H_2O_2 is predicted to have a detonation velocity of 6.68 km/s and a C-J pressure of 130 kbar.

Hydrogen peroxide was shock compressed at pressures up to the von Neumann pressure for a steady detonation wave, using ultrafast laser-driven shockwave methods [1043]. At higher laser drive energy, evidence of exothermic chemical reactivity occurring in less than 100 ps after the arrival of the shockwave in the sample were found. The results were consistent with molecular dynamics simulations and analysis and suggested that reactivity in hydrogen peroxide is initiated on a sub-100 ps

timescale under conditions found just subsequently to the lead shock in a steady detonation wave.

Pyroshock from firings of adjacent pyrovalves or explosive separation bolts may initiate explosions in highly concentrated hydrogen peroxide [1044].

9.4 Card Gap Sensitivity of Hydrogen Peroxide

Card gap tests, using an apparatus in which 30 g of liquid sample was separated from a 30 g tetryl charge by a thin (5 to 10 mils) aluminum membrane, indicated no evidence of detonation in 90, 95, or 98% hydrogen peroxide. The results were similar to those resulting from earlier tests conducted by the US Navy [1045] to demonstrate the relative insensitivity of 90, 95.5, and 99.5% hydrogen peroxide at ambient temperatures and 344 K (160 °F).

Results of card gap sensitivity tests with several different concentrations of HTP were described in [1039] (Table 66).

Table 66: Card gap test results with hydrogen peroxide.

H ₂ O ₂ concentration, mass-%	Number of cards required to obtain negative results	
	Ambient temperature	344 ± 3 K = 160 ± 4 °F
90%	0	16
95.5%	7	25
99.5%	9	23
For comparison: Cavea B 110	12	27

Data source: [1039]

However, in the NOL Large Scale Card Gap Test, 98% HTP at 286 K (13 °C) had a 50% point of positive at 35 cards corresponding to an attenuated shock pressure of 90 kbar [1046].

9.5 Boosted Detonation Shock Sensitivity Tests (Without Spacers)

The sample temperature plays a significant role in determining the ability of hydrogen peroxide to propagate a detonation. The temperature necessary to cause a propagating detonation decreases appreciably with increasing concentration of hydrogen peroxide.

From early German investigations in the 1940s, it was reported that the H₂O₂-H₂O system can detonate at velocities of 6000–7000 m/s when the H₂O₂ concentration is

96% or greater. Below 96% it was found to be more difficult to obtain a propagating detonation at ambient temperatures.

Tests at Degussa paralleled earlier work that showed that 99% hydrogen peroxide can be detonated at ambient temperature in a 2 or 4 ft. length of an 1-in. ID pipe (0.17 in. wall thickness) using 20 g tetryl as the initiator [1047]. However, a 10-g charge of tetryl or the use of smaller diameter pipes (0.75 or 0.5 in.) did not induce a propagating detonation.

In tests at Degussa, the card gap test [1048] was modified by using a booster charge of 320 g of RDX/wax/graphite (95/5/0.5) and a thin film of PE and a layer of PTFE tape with a total thickness of about 0.20 mm instead of a stack of cards prepared of cellulose acetate (of thickness 0.19 mm). A propagation of detonation was confirmed for 98.8% H_2O_2 at “zero gap” (0.19 mm, corresponding to one card) yielding a completely fragmented tube (51 fragments, 14% of the tube mass was recovered) and a large hole punched into the lead witness plate [99, 100]. The detonability boundary in a 51-mm (2-in.) diameter charge as a function of H_2O_2 concentration and sample temperature is shown in Figure 60.

Figure 60: Results of 2-in. diameter steel tube tests as a function of H_2O_2 temperature and concentration. (Reproduced and modified [99], with permission granted by Evonik Operations GmbH.)

Subjecting a sample of identical concentration (98.8%) to the procedure with a PMMA spacer (corresponding to a stack of 240 cellulose acetate cards) did not yield a propagation of the booster detonation. These results showed that the sensitivity of H_2O_2 does not meet the criteria to be classified as an explosive.

9.6 Adiabatic Compression Sensitivity of Hydrogen Peroxide

Adiabatic compression tests with 70% H_2O_2 at ambient temperature and at 334 K (160 °F) showed the material to be insensitive at pressurization rates as high as 231000 psi/s. Even with the more concentrated samples, adiabatic compression tests of 90 and 98% H_2O_2 gave no detonative effects at 294 or 334 K (70 or 160 °F) when subjected to a maximum loading rate of 231000 psi/s [99, 100, 1039].

Somewhat similar tests using 90% H_2O_2 driven with 2000 psi air pressure against the closed end of a 1.250-in. ID pipe were reported by Bellinger [482]. He observed no explosions in these tests or in tests in which the H_2O_2 was driven through a 0.250-in. hole in the end of the pipe. Other tests concluded that 90% H_2O_2 is insensitive to adiabatic compression at all initial liquid temperatures up to 394 K (121 °C = 250 °F) and at pressurization rates up to about 200000 psi/s.

Ordinary shutdown transients and water hammer pressure spikes occurring in the feed system of satellite propulsion subsystems when valves are shut abruptly should not be sufficient to initiate decomposition of hydrogen peroxide but may damage valve seats or rupture burst diaphragms of relief valves [1049]. However, in the X-15 rocket plane, some damage was observed initially before slower acting valves were installed in the HTP system [1050].

9.7 Other Detonation Hazards of Hydrogen Peroxide and Its Mixtures

9.7.1 Other Detonation Hazards of Hydrogen Peroxide

According to Solvay Interlox, 70% hydrogen peroxide solutions are not detonable, even when boiling at atmospheric pressure. Strengths of 80% and above can be made to explode but only with difficulty. The conclusion of Solvay Interlox is that 85% H_2O_2 is capable of detonation at temperatures of 318 K (45 °C) and above if significant initiation sources are also present. These conclusions are derived primarily from tests that employed initiation by a combination of No. 8 detonator and 50-gram booster charge. This energy of initiation is not judged to be realizable from normally encountered sources associated with chemical handling on a plant (e.g., water hammer, pump malfunction, impact, thermal shock); rather an actual adjacent detonation would be needed (e.g., a mixture of 85% H_2O_2 /organic or some stronger H_2O_2 alone). The question of whether a H_2O_2 vapor explosion (see above) can transmit into a liquid phase detonation was considered by Solvay Interlox, and it was their understanding that this event is not possible, or at worst, extremely remote.

9.7.2 Detonability of Mixtures of Hydrogen Peroxide with Other Oxidizers

Hydrogen peroxide with 90 and 99% H_2O_2 , an oxidizer mixture containing 55% H_2O_2 , 39% ammonium nitrate, and 6% water, and a monopropellant mixture containing

67.8% H_2O_2 , 6.6% diethylene glycol, and 25.6% water were thoroughly characterized in drop weight impact sensitivity, cap sensitivity, boosted detonability, card gap sensitivity, and adiabatic compression sensitivity tests, at room temperature and even at elevated temperature [1051]. It was concluded that all four propellants are so insensitive to mechanical and hydrodynamic shock and to adiabatic compression that might be encountered during field use that no real hazards exist in handling them in the field.

9.7.2.1 Detonability of Liquid Mixtures of Hydrogen Peroxide with Organic Compounds

Mixtures of liquid H_2O_2 with organic compounds must be avoided because they may be shock sensitive and detonable [1052, 1053]. In an effort to increase the specific impulse of hydrogen peroxide monopropellants, mixtures of hydrogen peroxide with ethanol were tested in Germany in the mid-1930s. This resulted in a disastrous explosion, but details of the accident could not be obtained. The explosive limits of hydrogen peroxide mixtures with ethanol, acetone, or glycerol are illustrated in Figure 61.

Figure 61: Detonable range in liquid hydrogen peroxide/organic fuel mixtures. (Reproduced and modified from Laporte Chem. Ltd.)

The detonability of mixtures of hydrogen peroxide, soluble organic fuels and water was tested, and a correlation was found between the detonable range and the theoretical heat of explosion [1053, 1054]. The boundaries of the explosive range in the ternary diagram depend on the mode of initiation. The range of drop weight sensitivity is narrower than the range of cap sensitivity. Figure 62 and 63 give the detonable ranges of mixtures of hydrogen peroxide with ethanol or glycerol with water as the diluent and initiation by a blasting cap [1055]. Similar data were available for acetone or tetrahydrofuran as the organic fuel. Similar, but less detailed graphs were shown in publications by Shanley and Greenspan [367] and Shanley and Perrin [1053].

Figure 62: Range of explosive compositions for hydrogen peroxide-ethanol-water mixtures, three different modes of initiation. (Republished and modified from [1053], with permission of © 1958 American Institute of Aeronautics & Astronautics; permission conveyed through Copyright Clearance Center Inc.)

Figure 63: Range of explosive compositions for hydrogen peroxide-glycerol-water mixtures, three different modes of initiation. (Republished and modified from [1053], with permission of © 1958 American Institute of Aeronautics & Astronautics; permission conveyed through Copyright Clearance Center Inc.)

Mixtures of hydrogen peroxide and fuels may detonate with more than one characteristic speed of detonation. Sometimes a transition is observed from one mode of detonation to another as the detonation front propagates through the sample.

The above studies of the explosive limits of hydrogen peroxide/water systems containing methanol, ethanol, or glycerol defined the regions of detonable compositions at room temperature. A subsequent study was made to assess the effect of temperature and type of initiation on mixtures of hydrogen peroxide and water with various organic compounds, such as 2-propanol, all of which are soluble in hydrogen peroxide [1056]. Several types of initiation were used: impact, blasting cap, and a high-velocity shockwave. For some compositions, the overall reaction between the organic materials and hydrogen peroxide can proceed at a rate such that a stable detonation wave is propagated through the liquid. Near the limits determined by impact or blasting cap, however, the reactions are more nearly characteristic of rapid deflagration or explosion than of sustained detonations. In all these instances, the force of the reaction is sufficient to lead to the destruction of containers and considerable damage to the surroundings. Two types of impact testers were used during the investigation: The simpler of these was a modification of the test apparatus described by Bellinger [365]. The piston and cylinder (1.375 in. and 1 in. long, respectively, and 0.3 ± 0.0002 in. in diameter, lapped to fit) were of hardened tool steel for greater reproducibility of the impact shock. The striking blow was delivered by a 360-gram weight falling from a height of 180 cm. The other apparatus was designed to study the effect of higher temperatures on the explosion limits. A 500-g weight falling 200 cm was to drive the piston into the chamber containing the test solution. The steam jacket around the cavity allows the rapid attainment of elevated temperatures (within 20 to 30 s) just prior to the moment of impact. The packing gland prevented evaporation of liquid from the hot sample.

The limits of explosion for the 2-propanol-aqueous hydrogen peroxide mixtures were measured by impact test at 294 and 406 K (21 and 133 °C), using the second tester described above. Increasing the temperature of the system to 406 K (133 °C) resulted in a small widening of the limits of explosion as measured by impact tests. Similar results were obtained when 2-propanol was substituted with a mixture of 75% 2-propanol and 25% acetone. Other organics tested included methanol, formaldehyde, acetaldehyde, propionaldehyde, formic acid, and 70% acetic acid.

The third method for initiating explosion of H_2O_2 /organics mixtures was by means of a high-energy shockwave like a card gap test without spacers. A 1- to 4-L sample was placed in a cylindrical tube on top of a booster charge consisting of a 2-in.-thick block of Composition B high explosive, which has a detonating pressure of approximately 270 kilobars. The Composition B pad was initiated with a plane wave generator. The mixtures of hydrogen peroxide and organic material that underwent steady detonation maintained detonation velocities as high as 6500 m/s. This compares to the high-velocity detonation of 7700 m/s reported for nitroglycerin.

Figure 64 shows the drop weight impact and cap sensitivity explosion limits in the ternary $\text{H}_2\text{O}_2/i\text{-C}_3\text{H}_7\text{OH}/\text{H}_2\text{O}$ system. The stoichiometric reaction taking place in these mixtures is

Figure 64: Drop weight impact and cap sensitivity explosion limits of ternary $\text{H}_2\text{O}_2/i\text{-C}_3\text{H}_7\text{OH}/\text{H}_2\text{O}$ mixtures. (Reproduced and modified from [1055].)

Since combustible organic liquids are used in the production of hydrogen peroxide by oxidation methods, hazards may be created by the presence of the combustibles in the peroxide liquid and vapor during such a process [1057]. The flammability of vapor mixtures of hydrogen peroxide at 427 K (154 °C) and 101 kPa with *o*-xylene and water was measured in a 1-in. diameter by 15-in. length Pyrex[®] tube. Hydrogen peroxide solutions with 55–70 mass-% H_2O_2 in mixtures with formic acid, acetic acid, or tartaric acid or xylene were tested for detonability in the card gap test, and the results presented in a triangular diagram and also as a function of carbon content. A sample with 67.5% H_2O_2 detonated. Thus, certain purge liquors formed in hydrogen peroxide

production can detonate when adequately stimulated if the organic material is permitted to build up to a sufficiently high concentration.

The detonability of hydrogen peroxide/glycerol mixtures was examined at the US Bureau of Mines [1058].

The use of hydrogen peroxide as an oxidant for organic chemical reactions (e.g., epoxidation) in the chemical processing industry can cause serious hazards. Some incidents due to runaway reactions of hydrogen peroxide with organics are described in [1059].

The explosive properties of mixtures of aqueous H_2O_2 and several different alcohols like 2-propanol, 2-methyl-2-propanol, 2-methyl-2-butanol, and 2-methyl-2-pentanol have been investigated [1060]. Among others, the potential hazard of such mixtures may be characterized by their ability to react to different stimuli leading to an explosion in the condensed phase, e.g., a thermal explosion or a detonation. Accordingly, the mixtures were tested either by heating them up under confinement in different autoclaves or by exposing them to a shockwave impact applying the steel tube test. The results are summarized in Figure 65.

Figure 65: Thermal explosion ranges of H_2O_2 /alcohol mixtures obtained in TEVT version B. (Republished and modified from [1060], with permission of © 2004 Elsevier Science & Technology Journals; permission conveyed through Copyright Clearance Center Inc.)

Sadly, mixtures of hydrogen peroxide and alcohols and mixtures of hydrogen peroxide with solid fuels have been used by terrorists in bombing attacks [1061].

Cook-off experiments performed on 70% H_2O_2 and sucrose compositions, as well as an acid-sensitized mixture showed that at soak temperatures of 355 to 361K

(82 to 88°C) the time to cook-off was 3010 to 3560 s [1062]. The experiments were performed in 10.16 cm (4 in.) diameter by 10.16 cm (4 in.) high, sealed aluminum containers heated externally with electric heating tape wrapped radially around the container. There were four internal and five external thermocouples to control the heater and to record sample temperature and exotherms. The energetic mixture was composed of four parts 70% H_2O_2 and one part sucrose. The mass used was 993 g (794 g H_2O_2 , 199 g sucrose), which filled 750 mL of a total internal volume of 825 mL. One experiment used a fuel mixture containing mostly sucrose, but with some citric and ascorbic acid. After assembly, the apparatus was heated to a predetermined soak temperature of either 361, 357, or 355 K (88, 84, or 82°C) and held there isothermally, until the energetic material ignited. The acid-sensitized mixture, when soaked at 355 K (82°C), reacted much faster than even the 361 K (88°C) acid-free experiment and burst the apparatus after just 2450 s. The acid caused the material to be thermally sensitized.

Mixtures of HTP with organic fuels have been considered as industrial explosives with low NO_x emission levels, suitable for underground mining [1063].

Difficulties with ignition of aerosolized HTP and kerosene led to a more detailed study of two-phase detonation properties of HTP/kerosene aerosols [1064]. Experimental attempts to generate a detonation in a liquid fuel drop (kerosene)-liquid oxidizer drop (50% hydrogen peroxide in water)-inert gas-environment were not successful. A vertical detonation tube, 4.1 cm (1 5/8 in.) diameter and 3.65 m (12 ft) long, was used for these studies. The blast wave was generated by the detonation of GH_2 and GO_2 at initially elevated pressures. While it was difficult to judge in some cases, the conclusion reached was that detonation of the aerosol mix was not realized. Stronger peroxide solutions, other liquid combinations, smaller drop sizes, and larger detonation tube cross section would be appropriate to demonstrate detonability of such aerosol suspensions.

9.8 Detonation of Hydrogen Peroxide Vapors

Whereas it is difficult to get liquid hydrogen peroxide to detonate, H_2O_2 vapors can detonate only too readily and sometimes unexpectedly. The situation is, thus, like that with hydrazine liquid and hydrazine vapors.

A vapor detonation is a chemical reaction coupled with a multiple shockwave system that propagates at supersonic velocities in reference to the unreacted vapor. After initiation, the thermal energy of the reaction sustains the shockwave, and the shockwave compresses the unreacted material to sustain the reaction. To assess a potential explosion hazard due to detonation, the following information must be known:

- pressure and temperature of H_2O_2 vapor
- atmosphere diluents, presence of incompatible or reactive materials and their concentrations

- ignition sources and the amount of energy released by the source
- type of confinement

Early investigators working with H_2O_2 vapors reported somewhat contradicting results for explosive decomposition limits, depending on the type of apparatus used, the presence or absence of non-inert surfaces, and the mode of initiation. In a 3-cm diameter Pyrex[®] tube at 373 K (100 °C), thermal decomposition flames and explosions were very readily initiated by a hot wire or a spark when the pressure was about 2.6 kPa (20 mm Hg) or higher [1065]. At atmospheric pressure the explosion was very violent and potentially initiated by catalytic spots on imperfectly cleaned glassware. The minimum temperature to which a wire must be heated to cause immediate ignition of the vapor at atmospheric pressure was about 873 K (600 °C).

The explosive characteristics of hydrogen peroxide vapor at atmospheric and sub-atmospheric pressures, including values for the ignition limit over this pressure range and the effect of the nature of diluent gases and the method of initiation on the limit have been reported by several authors [770, 771, 1066]. Most studies bracketed the concentration, pressure, and temperature envelope within which the H_2O_2 decomposition (not necessarily the detonation) can propagate. At atmospheric pressure, vapors containing 26.0 mol-% or more hydrogen peroxide could be exploded by initiation with a hot wire or spark gap. The ignition limit was unchanged by the system of ignition used, by varying the temperature of the hot wire between 1350 and 1750 K or by changes in the hydrogen peroxide-oxygen ratio in the diluent gas. The ignition limit increased to 33 mol-% hydrogen peroxide at 26.6 kPa (200 mm Hg) total pressure and to 55 mol-% hydrogen peroxide at 5.3 kPa (40 mm Hg). Vapors lying within the explosive composition region at 1 atmosphere total pressure may be exploded by contact with catalytically active material initially at room temperature or by “non-catalytic” materials like aluminum at temperatures of 423 K (150 °C) or higher. Decreasing the system volume by packing it with Raschig rings shifted the ignition limit to higher H_2O_2 concentrations.

The term “ignition limit” as used here is defined as the minimum concentration of hydrogen peroxide in a vapor mixture below which powerful external ignition cannot initiate a self-propagating reaction. The self-propagating reaction must not but can be a detonation. The propagation must not necessarily be a detonation, as will be discussed below.

The explosive limits of hydrogen peroxide vapors were examined at various partial pressures and in dilution with different inert gases [729, 779]. Based on those experiments, the lower limit of detonability at sea-level atmospheric pressure is 25.6 mol-% H_2O_2 (balance is H_2O steam). If the pressure is increased, the limit is lowered to 20.7 mol-% H_2O_2 and remains at that level for pressures from 202 to 606 kPa (2 to 6 at). At 26.6 kPa (200 mm Hg) pressure the $\text{H}_2\text{O}_2/\text{H}_2\text{O}$ vapor mixtures become detonable only if they contain 33 mol-% H_2O_2 . If the pressure is lowered further to 5.3 kPa (40 mm Hg), the mixture must contain at least 55 mol-% H_2O_2 to

sustain a detonation. Ignition can occur not only with a hot wire and a spark gap, but also by contact with catalytic materials. Inert gases have no different effect (no different than steam). Only carbon dioxide appears to have a weak inhibiting effect on ignition and the boundary of detonability is shifted toward higher H_2O_2 concentrations.

Satterfield and coworkers extended the pressure range over which the explosion limit was previously established to the range of 101 to 653 kPa (14.7 to 95 psia.) [772, 1067]. Instead of starting with H_2O_2 of the desired concentration, the experiment was part of a still in which 40 mol-% H_2O_2 could be concentrated until the explosive limit in the vapor phase was reached. The test vessel was a 300-mL borosilicate glass bulb at the top of a distillation column. The entire apparatus could be placed inside a pressure vessel, pressurized with nitrogen, and operated remotely. Ignition was done with a spark between electrodes connected to a Tesla coil. The only materials that came in contact with H_2O_2 vapor were borosilicate glass, aluminum wire, and Teflon. Between 202 and 606 kPa (2 and 6 atm) pressure, the ignition energy limit was found to be constant at 20.7 mol-% H_2O_2 in the vapor. The minimum concentrations for explosive propagation were found to be 25.6 mol-% at 101 kPa (1 atm) and 20.7 mol-% in the 202 and 606 kPa (2 and 6 atm) region.

Quenching distances and minimum ignition energies of $\text{H}_2\text{O}_2/\text{H}_2\text{O}$ vapor mixtures were studied in a flow system in which liquid $\text{H}_2\text{O}_2/\text{H}_2\text{O}$ was fed to a boiler where it completely vaporized and then passed through the explosion vessel holding the ignition source [1068]. The quenching distances and minimum spark ignition energies of mixtures containing between 35 and 50 mol-% H_2O_2 were determined at pressures between 3.3 and 26.6 kPa (25 and 200 mm Hg) at temperatures 9°C above the condensation temperature. The quenching distances varied between 0.51 and 1.63 cm and the ignition energies between 0.53 and 25.5 millijoules, decreasing with increasing H_2O_2 content and pressure. The observed minimum energy for ignition is related to the quench distance by:

$$E_{\min} = 3.84 \times d_q^{3.04}$$

where $E_{\min}$ is the minimum ignition energy in millijoules, and d_q is the quench distance in cm.

Earlier work by Satterfield et al. had measured explosion limits in the $\text{H}_2\text{O}_2/\text{H}_2\text{O}/\text{diluent}$ system only at pressures near 0.7 kPa (1 psia). Monger et al. [1069] expanded the measurements over a wider pressure range from 0.7 kPa to 6.8 MPa (0.1 to 1000 psia). Three types of apparatus were used: **(1)** A stainless steel apparatus that measured 17.8 cm (7 in.) O.D. and 66 cm (26 in.) in length. **(2)** A 300-mL glass bulb with and without a glass coil. **(3)** The other apparatus was made of aluminum, had an I.D. of 49 mm (1.939 in.) and was 2.43 m (8 ft.) long but was used only for lower pressure tests. Ignition was achieved with a spark from two 28 μfarad capacitors in series charged to 1500 V. In a few cases, the vapors ignited on their own by contact with a hot spot on a wall. Instead of having a stagnant vapor reservoir in the test

chamber, the hydrogen peroxide vapor flowed constantly through the apparatus to make sure that it was always fresh and had not deteriorated before the spark was energized. The only damage to the equipment occurred as the result of a test at 20 kPa (2.9 psia) using 77.8 mol-% H_2O_2 in the 300-mL glass bulb. Upon sparking, there was a sharp report, and the entire coil and the reboiler section were shattered. A 35 mol-% H_2O_2 mixture will detonate at 2037 m/s (6700 ft/s) at 101 kPa (1 atm). The ignition limit under these conditions is about 30 mol-% H_2O_2 vapor. The superatmospheric and subatmospheric pressure ignition limits of hydrogen peroxide are illustrated in Figure 66 and 67.

Figure 66: Ignition limit of hydrogen peroxide vapors at above atmospheric pressure. (This chart was created by Schmidt 2020 based on data from [1069].)

Note: The open symbols indicate negative tests (no detonation), and the solid symbols indicate positive tests (detonation). The dashed line in Figure 67 indicates the earlier data from Satterfield, which agree quite well with Monger's data.

The vapor space above 90% H_2O_2 becomes detonable only if the liquid is heated to at least 390 K (117 °C). If the vapor space above 100% H_2O_2 is tested, detonability will not be achieved unless the liquid is heated to at least 383 K (110 °C). These temperatures are not normally encountered during storage and transportation of HTP. Facilities for manufacturing and rocket engine testing with HTP will have to take the necessary safety precautions to prevent collateral damage in the event of an unexpected explosion.

Other experiments were conducted at 19.95, 46.6, and 101 kPa (2.90, 6.77, and 14.7 psia) in order to study the detonation characteristics of hydrogen peroxide vapor [1070]. Liquid $\text{H}_2\text{O}_2/\text{H}_2\text{O}$ solutions of the necessary concentration were fed to

Figure 67: Ignition limit of hydrogen peroxide vapors at below atmospheric pressure. (Reprinted and modified from [1069], with permission from © 1964 American Chemical Society; permission conveyed through RightsLink.)

a reboiler and the vapor passed through a detonation arrestor into the test section. Three different methods of initiation were used: One consisted of a 3500-V capacitive spark from the discharge of two 28 mfarad condensers across a 0.8-mm (0.031-in.) gap between two tantalum electrodes with hemispherical ends. Another form of initiation was provided by 1-in. firecrackers ignited with a resistance wire. Sometimes the mixture would ignite spontaneously before the other mode of initiation could be activated. The detonation tube was a length of 51-mm (2-in.) OD Sched. 80 Type 6063-T6 aluminum pipe fitted with a tee and blowout disk at each end. The inside diameter of the pipe was 49 mm (1.939 in.), and the assembled length was 2.43 m (8 ft.) The tube was radiatively heated with external heating rods to temperatures up to 423 K (150 °C). Within the experimental conditions employed, no detonations were observed at 19.9 and 46.6 kPa (2.90 and 6.77 psia). At atmospheric pressure,

Figure 68: Detonation velocity of $\text{H}_2\text{O}_2/\text{H}_2\text{O}$ vapor mixtures at atmospheric pressure. (Reprinted and modified from [1070], with permission from © 1964 American Chemical Society; permission conveyed through RightsLink.)

detonation with a velocity of 2037 m/s (6700 ft/s) was observed in vapor with a composition of 35 mol-% hydrogen peroxide. The mixtures became detonable as the H_2O_2 concentration was increased from 30 to 35 mol-%. Between 30 and 35 mol-%, several concentrations were tested in 1% increments. Compositions above 35 mol-% could not be tested because they had a tendency to explode prematurely before the spark could be energized. The data (Figure 68) showed a gradual, linear transition from the velocity-of-sound decomposition wave to the detonative mode. At the two lower pressures, decomposition waves propagated through the mixtures near or below the velocity of sound, but substantially below the calculated, theoretical CJ detonation velocity. Such decomposition events, if they happened in a distillation tower or in a storage tank, would still be quite destructive, but they would not be true detonations in the exact sense of the word.

Addition of aluminum powder to 98% H_2O_2 makes a very powerful explosive [1071]. In an experiment, 40 μm amorphous aluminum powder was suspended by gelling 90% hydrogen peroxide with a carboxy polyvinyl chloride. Stable detonation rates were measured for well-confined compositions of both types balanced stoichiometrically to alumina and steam. The concentration of hydrogen in the reaction products of a series of aluminum-hydrogen peroxide charges with oxygen balances rising toward zero decreased and became negligible. Pressures of 95 kilobars or higher were achieved by this mixture when initiated with 100 g tetryl. Experimental results from these charges were compared with Ruby code calculations of reaction products for a charge balanced to alumina and steam and also with data from experiments with water immersed torpexes. As part of this program, the detonation rate of aqueous hydrogen peroxide (97.5%) by itself without any fuel added was measured and compared with values found in prior German work and with a Ruby code calculation. Detonation velocities of aq. H_2O_2 (96+%) without fuel addition under heavy confinement and strong boosting were measured by a smear camera

under the following conditions: A 1530 g charge, 7.6 cm diameter, 24.0 cm length, was loaded in a glass cylinder (2.5 mm wall) confined by a tightly fitting, mild steel sleeve (3 mm wall). Initiated by 100 g tetryl, the charge reacted at 6440 m/s with no measurable drop in velocity over its length. A 2.54 cm thick steel witness plate under the charge was perforated to a diameter about equal that of the charge. The sensitiveness of aq. H_2O_2 (97.5%) to shock initiation was measured by the large-scale gap test. In this test, 230 g aq. H_2O_2 (97.5%) were confined in a steel cylinder of 3.66 cm ID, 0.56 cm wall, and separated from a standard tetryl donor by a cellulose acetate gap. The cellulose acetate thickness was varied in successive shots to obtain a 50% initiation gap. This gap for aq. H_2O_2 (97.5%) was 35 cards or 0.35 inches and is compared with gap sensitivities of two well-known explosives and a double-base propellant in Table 67.

Table 67: Comparison of large scale gap sensitivities of aqueous H_2O_2 (97.5%) and other energetic materials; 50% initiation probability gap.

Composition	Density	% Theoretical maximum density	No. of cards
AHH double-base propellant	1.60		36
Aqueous H_2O_2 (97.5%)	1.44		35
TNT (cast)	1.62	98	138
Composition B (cast)	1.70	99	201

9.9 Explosive Yield of Hydrogen Peroxide in the Lead Block Test

In addition to the go/no go detonability tests discussed above, the explosive power of 85.5% H_2O_2 mixtures with methanol, ethanol, and glycerin was measured in the Trauzl lead block test, and the detonation velocity was measured as well [1038]. The lead block indentations approached those measured with nitroglycerin and exceeded those of picric acid.

9.10 Bonfire Tests of Hydrogen Peroxide Tanks

The H_2O_2 tanks in which a foreign hydrogen peroxide product was to be shipped were to be constructed from 99.5% aluminum. The US Coast Guard does not normally allow the use of aluminum for tank construction because of its poor high temperature strength. In this case, however, pure aluminum was necessary to minimize the decomposition rate of the cargo. Engineering estimates were made to study the effect of a vigorous external fire on a nominal 15 m^3 (4000 gallon) bare aluminum tank con-

taining 70% hydrogen peroxide [396]. Decomposition rates of 70% hydrogen peroxide over a temperature range up to and above the normal boiling point (398 K = 125 °C for 70 mass-% H_2O_2) were measured. Previously reported work on hydrogen peroxide stability was done mostly with 90% material. Reproducibility of results was a problem at 373 K (100 °C) and above, and therefore a lower temperature was commonly employed for these tests, for example 323 K (50 °C). In this analysis, the problem decomposition rates of significance are those at: **(1)** the ambient temperatures encountered in transportation and **(2)** the temperatures resulting from a fire situation, especially the decomposition rate up to the boiling point at the relief pressure of the 4000-gallon tank. Pressure is said to have no effect on the rate of decomposition. The decomposition reaction of hydrogen peroxide is not reversible.

10 Oxonium and Peroxonium Salts

Peroxonium salts are of interest as solid propellant oxidizers and as potential sources of singlet atomic oxygen for chemical lasers. The peroxonium salts discovered so far are not very stable, and additional work is required to develop proper stabilization techniques.

The first known examples of peroxonium salts $[\text{H}_3\text{O}_2]^+ [\text{Sb}_2\text{F}_{11}]^-$, $[\text{H}_3\text{O}_2]^+ [\text{SbF}_6]^-$, and $[\text{H}_3\text{O}_2]^+ [\text{AsF}_6]^-$ were prepared by protonation of H_2O_2 in anhydrous HF solutions of the corresponding Lewis acids [1072, 1073]. These salts would be powerful oxidizers and are a means to store H_2O_2 in solid form. They were isolated as metastable solids, which underwent decomposition to the corresponding H_3O^+ salts and dioxygen, in the temperature range 293–323 K (20–50 °C). The $[\text{H}_3\text{O}_2]^+$ salts were characterized by vibrational and NMR spectroscopy. Attempts to protonate both oxygen atoms in H_2O_2 to form $[\text{H}_4\text{O}_2]^{2+} [\text{SbF}_6]^-$ resulted in $[\text{H}_3\text{O}_2]^+ [\text{Sb}_2\text{F}_{11}]^-$ as the only product.

11 Alkali Metal and Alkaline Earth Metal Peroxides

The alkali and earth alkaline metal peroxides are strong oxidizers, but they are not used as solid rocket propellants due to their moisture sensitivity. A common use of several of these materials is in breathing air regeneration oxygen cartridges where the acidity of exhaled carbon dioxide along with moisture of exhaled air releases breathable oxygen.

11.1 Lithium Peroxide

In the group of alkali metal peroxides, lithium peroxide, Li_2O_2 , CAS RN [12031-80-0] surprises by its poor solubility in water (8%). Lithium peroxide solutions are stable but

will decompose in the presence of manganese or iron salts or silver catalysts [1074]. Lithium peroxide is used in air revitalization life support units where weight (mass) is important and justifies the higher price of Li_2O_2 compared to the use of Na_2O_2 , e.g., in crewed spacecraft (Apollo) to absorb carbon dioxide and release oxygen in the reaction:

This reaction is the same for the other alkali metal peroxides. Lithium peroxide absorbs more CO_2 than the same mass of lithium hydroxide and offers the bonus of releasing breathable oxygen.

11.2 Sodium Peroxide

Most metals when burning in oxygen or air would result in the formation of the metal oxide. Not so with sodium and some of the other alkali and earth alkaline metals. Sodium metal burning in oxygen or air will result in the formation of sodium peroxide Na_2O_2 and not sodium oxide Na_2O . Sodium peroxide, Na_2O_2 , CAS RN [1313-60-6] is a yellowish solid, often supplied in spherical granules. Sodium peroxide dissolves in water with the release of heat, initially forming a hydrate $\text{Na}_2\text{O}_2 \cdot 8\text{H}_2\text{O}$ and on further dilution slowly hydrolyzes to an alkaline solution of NaOH and H_2O_2 :

Other hydrates and peroxohydrates formed are $\text{Na}_2\text{O}_2 \cdot 2\text{H}_2\text{O}_2 \cdot 4\text{H}_2\text{O}$, $\text{Na}_2\text{O}_2 \cdot 2\text{H}_2\text{O}$, and $\text{Na}_2\text{O}_2 \cdot 2\text{H}_2\text{O}_2$. Organic materials in contact with sodium peroxide may autoignite.

When used in air revitalization units to absorb CO_2 , an intermediate compound $\text{Na}_2\text{C}_2\text{O}_6$ may form before all oxygen is released.

Waterless reactions between solid alkali metal or alkaline earth peroxides and hydrogen (deuterium) halide gases can produce singlet Δ oxygen for a chemical laser in a non-liquid medium [1075–1078]. These reactions occur under ambient conditions without the need for an external energy source. The production of singlet Δ oxygen was verified by direct emission spectroscopy at $1.27\text{ }\mu\text{m}$ with a calibrated optical multi-channel analyzer. These reactions overcome the quenching problems encountered in liquid-phase reactions and the dangers/inconvenience associated with the use of basic hydrogen peroxide liquids for the chemical oxygen iodine laser (COIL).

11.3 Potassium Peroxide and Potassium Superoxide

Potassium forms five types of oxides: potassium oxide K_2O , CAS RN [12136-45-7], potassium peroxide K_2O_2 , CAS RN [17014-71-0], potassium superoxide (“potassium hyperoxide”), KO_2 , CAS RN [12030-88-5], the less common potassium trioxide K_2O_3 , and

potassium ozonide KO_3 . In dry air, potassium oxide K_2O absorbs oxygen and transitions into potassium peroxide K_2O_2 . Potassium peroxide hydrolyzes readily with water to form potassium hydroxide and oxygen:

Potassium superoxide can be produced by burning molten potassium metal in pure oxygen. It is a yellow solid. When dissolving potassium superoxide in water, an unidentified short-lived, blue-colored intermediate can be observed. Potassium superoxide is often used as an oxidizing agent in industrial chemistry, as a CO_2 scrubber and oxygen generator in rebreathers, spacecraft, submarines, and spacesuit life support systems. Potassium ozonide, KO_3 , is a dark red solid that is produced when potassium metal is burned in ozone.

11.4 Calcium Peroxide

Calcium peroxide, CaO_2 , CAS RN [1305-79-9], is an off-white solid peroxide. It is practically insoluble in water but will dissolve in acidic water to form hydrogen peroxide. When in contact with water it will slowly decompose, releasing oxygen. In the bread baking industry calcium peroxide is used as a flour bleaching agent, but mixtures of calcium peroxide and flour in the wrong ratio are potentially explosive.

11.5 Barium Peroxide

Barium peroxide, BaO_2 , barium dioxide, CAS RN [1304-29-6], is a gray-white solid. Barium peroxide is an oxidizing agent, which can be used for bleaching of cellulosic materials, fabrics, and as an oxidizer in pyrotechnic formulations.

Barium peroxide is formed during the combustion of barium metal in oxygen or by the reversible absorption of atmospheric O_2 by barium oxide. The oxygen is released if barium peroxide is heated above 1100 K

This reaction was the basis for the now-obsolete Brin process for separating oxygen from the atmosphere and the first process for production of hydrogen peroxide:

Hydroxylammonium Salts

Books on rocket propellants have undergone significant changes during updating in the twenty-first century. One of the most prominent changes is the inclusion of new chapters on hydroxylammonium salts, which were never even mentioned in the old books but have now evolved into an interesting family of potential rocket and liquid gun propellants.

Because the hydroxylammonium cation contains one more oxygen than the ammonium cation, salts of hydroxylamine with oxidizing acids make better oxidizers than ammonium salts. In the form of their aqueous solutions they can be used in monopropellants, liquid gun propellants, and torpedo propellants (*Encyclopedia of Monopropellants*). Concentrated solutions of hydroxylammonium salts can also be used as liquid oxidizers in bipropellant engines or in hybrid rockets. This chapter on hydroxylammonium salts is preceded by a short summary of information on the free hydroxylamine base. Although too unstable to be used as a rocket propellant, hydroxylamine free base plays an important role in the slow and fast decomposition of hydroxylammonium salts. Aqueous solutions of the free hydroxylamine base can also be used as a starting reagent in the preparation of hydroxylammonium salts. This is why it is included here. The most important hydroxylammonium salt in this rocket propellant category is hydroxylammonium nitrate, $[\text{NH}_2\text{OH}^+][\text{NO}_3^-]$, HAN, and consequently the majority of the current chapter is devoted to it. Hydroxylammonium nitrate aqueous solutions must be maintained slightly acidic to prevent formation of hydroxylamine free base. The unwanted and uncontrolled presence of hydroxylamine free base accelerates the premature decomposition of HAN during storage.

1 Hydroxylamine Free Base

Hydroxylamine free base, NH_2OH , CAS RN [7803-49-8], HA (antiquated names are oxammonium and oxyammonia), is not used as a rocket propellant, but because it is either an intermediate or additive in the production of hydroxylammonium salts (for comparison: NH_2OH^+ ion, CAS RN [62675-55-2]) or closely related to some of the decomposition mechanisms of hydroxylammonium salts, we are including a tutorial chapter on it here. This serves as an introduction to the more detailed sections on hydroxylammonium salts, which have more practical uses than the free base. A HAN-based monopropellant has flown in a satellite propulsion system to demonstrate the feasibility of less toxic monopropellants. Hydroxylamine free base can be used for the preparation of HAN. Some of the hazards encountered when preparing and using hydroxylammonium salts are closely tied to the instability of the parent amine, hydroxylamine free base. For this reason, we are including in this book on propellant oxidizers two sections on the decomposition of hydroxylamine free base, first discussing the

mechanisms (which are closely interrelated with the mechanisms of decomposition of HA salts as monopropellants) and thermal decomposition kinetics. A discussion going beyond plain decomposition of HA, where actual experimental decomposition and actual flame studies are conducted, are included in a volume on monopropellants (*Encyclopedia of Monopropellants*). Hydroxylamine or hydroxylammonium are intermediates in the bacterial oxidation of ammonia to form nitrite and nitrate and in the reduction of nitrate by another set of bacteria. Nitrification in nature is a two-step oxidation process of ammonium (NH_4^+) or ammonia (NH_3) to nitrate (NO_3^-) catalyzed by two different types of bacteria. The first reaction is oxidation of ammonium to nitrite by ammonia-oxidizing bacteria (AOB) represented by the *Nitrosomonas* genus. These steps are carried out by two different groups of organisms, the ammonia-oxidizing bacteria and the nitrite-oxidizing bacteria. A key enzyme in nitrification is ammonia monooxygenase, which oxidizes ammonia to hydroxylamine. Another enzyme in action is hydroxylamine oxidoreductase. Hydroxylamine may exist in the gut of animals eating a nitrate-rich diet. There are thousands of tons of hydroxylamine in circulation in the bacterial world at any one time. There is plenty of ammonia in interstellar space and planetary ices, as well as hydroxyl radicals. Their reaction could lead to hydroxylamine, which would accumulate in the condensates at low temperature because it is less volatile. Hydroxylamine in interstellar space may react with acetic acid to form amino acids, the building blocks for life.

We discuss hydroxylamine free base here because even in salts of HA with strong acids, as in HAN, reverse dissociation that liberates a small amount of the free base in equilibrium with its salt is responsible for a lack of thermal stability in many hydroxylammonium salts in solution. The free base itself in the anhydrous state lacks sufficient thermal stability to be considered as a propellant or for any other application in the pure state by itself. In the pure state, it is better characterized as an explosive.

A short summary of hydroxylamine chemistry is contained in *Ullmann's Encyclopedia of Industrial Chemistry* [1], but it does not even mention HAN.

1.1 Preparation of Hydroxylamine Free Base

It is unlikely that rocket propellant chemists will need to prepare hydroxylamine free base in the laboratory, but the synthesis of some of the more energetic hydroxylammonium salts may start with the free base and an acid, doing a simple neutralization reaction.

Historically, the economic incentive for producing hydroxylamine solutions was driven by the desire to produce polyamides (nylon 66, etc.) in large quantities to satisfy the needs of the textile industry. Once one has a cheap source of hydroxylamine free base, it would be easy to produce all the other HA salts (HAN, hydroxylammonium perchlorate [HAP]) by a simple neutralization and concentration process. The polymer industry would use the free base to prepare cyclohexanone oxime, an inter-

mediate in nylon synthesis. In many industrial installations the hydroxylamine is not isolated as such, but dilute solutions of HA free base or hydroxylammonium salts are immediately processed into oximes and isolated as such. More than 95% of all hydroxylamine produced is used to make cyclohexanone oxime or caprolactam. The global production capacity of hydroxylamine is estimated to be 800000 metric tons/year. Industrial use and transport of hydroxylamine is not as the free base but is mainly as the sulfate salt, supplied as both an aqueous solution and solid crystalline material. Aqueous solutions of hydroxylammonium sulfate can be shipped in tank cars made of stainless steel or polyethylene. Crystalline hydroxylammonium sulfate is packed in polyethylene sacks. A small amount of HAN in the form of 24% HAN solutions is used for the reprocessing of nuclear reactor fuel elements.

Hydroxylamine free base in 50% aqueous solution is used for cleaning and photoresist removal of silicon chips in the production of integrated circuits and memory chips. It was during production of a 50% HA solution for this semiconductor application that two devastating explosions occurred in two different continents within a few years of each other. Distillation of hydroxylamine free base is a **hazardous** operation.

Hydroxylamine free base is sometimes used for the preparation of hydroxylammonium salts by neutralization with the acid of choice. But hydroxylammonium salts prepared from the free base may contain contaminants (stabilizers) carried over from the HA production process. Commercially available hydroxylamine free base as a 50% solution often contains proprietary stabilizers that would interfere with subsequent use of HAN in catalytic monopropellant reactors. If anhydrous hydroxylamine free base is needed, the commercially available aqueous 50% hydroxylamine solution can be dehydrated by distillation with *n*-butanol. This is a hazardous operation.

Methods for the production of hydroxylamine free base without starting with hydroxylammonium salts include the reduction of nitrate, the catalytic oxidation of ammonia [2], reaction of ozone with ammonia, reduction of NO/NO₂ in a solution of ammonium sulfite, reduction of NO with H₂ over a platinum catalyst, and many others.

1.1.1 Preparation of Hydroxylamine Free Base from Hydroxylammonium Salts

If small samples of pure hydroxylamine are needed for spectroscopic or other analytical purposes, they can be prepared by the historical method described by Hurd and Brownstein. This method starts with preparing a solution of sodium butoxide in *n*-butanol, which is then reacted with a dispersion of finely ground hydroxylammonium chloride in butanol while stirring, and observing the pH with a phenolphthalein indicator. The insoluble sodium chloride is filtered and washed with butanol, and the filtrate is chilled to 263 K (−10 °C). Hydroxylamine free base precipitates in large white flakes. It is collected on filter paper, washed with butanol and then with diethyl ether, and dried in a desiccator. The yield is 50% of theory.

The same method is described in a patent [3] (which also describes various stabilizing additives), although no credit was given to Hurd and Brownstein.

An older method is very similar and used sodium ethoxide instead of sodium butoxide

with essentially the same results [4].

Small amounts of hydroxylamine free base and also its deuterium isotopologue can be prepared by vacuum decomposition of hydroxylammonium orthophosphate, $(\text{NH}_3\text{OH})_3\text{PO}_4$, in partial vacuum with a stream of purge nitrogen [5].

The reaction of hydroxylammonium sulfate with sodium hydroxide gives a mixture of free base and sodium sulfate. The mixture is cooled to precipitate the sodium sulfate, and the filtrate can be distilled at reduced pressure in a stripper column with steam at $\sim 353\text{ K}$ ($\sim 80^\circ\text{C}$) to give a salt-free hydroxylamine distillate containing 8% NH_2OH that can subsequently be concentrated in a different distillation column such that 50% NH_2OH can be withdrawn at the bottom [6]. This is a **hazardous** operation.

The process as it was operated at Concept Sciences, Inc. in Pennsylvania and at Nissin Chemical in Gunma Prefecture in Japan consisted of a continuous stirred tank reactor (CSTR), multiple filtration units, and a packed distillation tower. The CSTR was fed with stoichiometric amounts of potassium hydroxide (KOH) and hydroxylammonium sulfate. The two streams combined in the reactor according to the following equation:

Preliminary studies indicate that KOH catalyzes the decomposition of HA; therefore, the mixture must be well mixed, and the reactants must be metered in slowly. The product stream from the reactor is fed to a filtration unit to remove the solid potassium sulfate. An accumulator may be used to isolate the preceding process (reaction and filtration) from the distillation. A heat exchanger with an outlet temperature control is also employed to achieve a suitable feed temperature for this stream, which consists of approximately 30 mass-% HA. The 30% HA stream is then fed to a vacuum distillation tower to concentrate it to 50 mass-% HA at the bottom. A packed distillation tower operating at 33 kPa (250 mm Hg) and a reflux ratio of 0.5 should enable the desired separation to obtain 50 mass-% HA product. This is a **hazardous** operation, and accidents that have occurred at facilities using this process are discussed in Section 1.4.

A high-purity aqueous solution of hydroxylamine free base can be obtained by treating an aqueous solution of a hydroxylammonium salt with a base such as ammonia at low temperatures [7]. The ammonium salt side product can be separated from hydroxylamine by low-temperature filtration and a resin-exchange process. The concentration of the hydroxylamine product is further increased by a distillation process that produces a high-purity and high-concentration hydroxylamine product with reduced risks of explosion.

A cation exchange resin can be loaded with hydroxylammonium ions from a solution of any hydroxylammonium ion, washed with water to remove contaminants, washed with a dilute hydroxylamine free base solution, and then treated with caustic having a dissociation constant greater than 10^{-7} (ammonia) to liberate the purified hydroxylamine free base. For preparation of free base by ion exchange from hydroxylammonium salt solutions, see [8–12]. An alternate use would be to extract the cation resin with strong nitric or perchloric acid to prepare the corresponding ammonium salts in high purity (albeit with an excess of acid).

An electrodialysis process using a bipolar cation exchange membrane starting with hydroxylammonium salts and liberating the free base at the cathode is described in a patent [13].

1.1.2 Preparation of Hydroxylamine Free Base from Nitric Oxide

There are several dozen patents for the preparation of hydroxylamine free base from nitric oxide, which is a cheap starting reactant. An excellent review of hydroxylamine production methods by reduction of nitric oxide was written by Tauszik and Crocetta [14]. The reduction of nitric oxide with hydrogen is carried out over platinum catalysts in sulfuric acid solution and would not lead to the free base but to a hydroxylammonium salt [15]. One type of catalyst is platinum deposited on activated charcoal with platinum contents in the range of 1.2–11.3 mass-% [16]. Similar methods aimed at hydroxylammonium salts instead of free base are discussed in Section 3.2.8.

Hydroxylamine can be made by partial reduction of nitric oxide. However, continuing the reduction of nitric oxide past the desired product, with hydroxylamine as the reductant, leads to ultimately useless nitrogen and water [17, 18].

The reduction of nitric oxide, NO, on gold electrodes in alkaline solutions leads directly to free HA [19]. This reaction can even be carried out in a fuel cell, where it produces electricity as an additional bonus in a cogeneration scheme [20]. The electrochemical cell typically consists of a porous gas-diffusion anode and cathode placed in two compartments that are separated by a proton-exchange membrane [21–23].

Among the several cathode electrocatalysts tested, iron-phthalocyanine impregnated in graphite was the most favorable one for selective synthesis of hydroxylamine [24].

1.1.3 Electrochemical Methods for Production of Hydroxylamine

The electrolytic reduction of NO may go through N_2O , HONO, and $(HONO)_2$ as intermediates. Polarographic measurements of electrode potentials show a multi-step process. The first polarographic step (0.8 to 0.65 V) corresponds to the formation of N_2O . The second step (0.45 to 0.22 V) is the reduction to NH_3OH^+ and NH_4^+ . The reduction of NO on gold electrodes in alkaline solutions leads directly to free HA [25]. A somewhat different apparatus uses a flow-through mercury-plated nickel electrode [26]. See also

[27–29]. Other investigators reduced nitric oxide on a porous platinum electrode to obtain hydroxylamine (or its salts) in good yields [30, 31].

A three-compartment cell with anion-selective membranes and cation-selective membranes separating the center compartment is fed with a solution of a hydroxylammonium salt to produce a solution of the free base in the catholyte [32]. One method for reducing the acid content of a solution and for converting a hydroxylamine salt to hydroxylamine uses an electrolysis cell consisting of an anolyte compartment containing an anode, a catholyte compartment containing an oxygen-consuming cathode, and an anionic membrane divider separating the two compartments. An aqueous solution of an acid is fed to the anolyte compartment, and an aqueous solution comprising the hydroxylamine salt is fed to the catholyte compartment. An oxygen-containing gas is bubbled through the cathode compartment [33]. This can be combined with a nitrate-reducing cell to produce the free base from nitric acid in a continuous process. In this case, the cell consists of a feed compartment between the cation-selective membrane and the anion-selective membrane, a recovery compartment between the cathode and the cation-selective membrane, and an acid compartment between the anion-selective membrane and the anode. Electrochemical processes for the production of HAN are described in Section 3.2.2.

1.1.4 Formation of Hydroxylamine Free Base by Oxidation of Ammonia

The most direct method for synthesis of hydroxylamine would be the oxidation of ammonia with oxygen or even with air:

Unfortunately, this reaction is not feasible, but a similar reaction with ammonia and hydrogen peroxide in the liquid phase over a titanium silicate catalyst is supposed to give some hydroxylamine [2]. Similar processes have been patented for the production of hydroxylammonium salts (Section 3.2.9). Ammonia oxide NH_3O forms as an intermediate during ammonia oxidation and quickly isomerizes to hydroxylamine [34], but both intermediates are too unstable to be isolated under the highly exothermic conditions of ammonia combustion. The problem is at least as difficult or even more difficult than the direct oxidation of methane to methanol.

The research in stabilization of hydroxylamine has been reviewed [35]. The decomposition mechanism, influence factors, and inhibition means of hydroxylamine and its salts are important for their use as propellants. The characteristics of related stabilizers were discussed and analyzed to provide guidance for stabilization research of energetic oxidizers such as HAN.

1.2 Physical Properties of Hydroxylamine Free Base

1.2.1 Physical and Mechanical Properties of Hydroxylamine Free Base

The introduction of one oxygen atom changes the properties of ammonia drastically. No longer is it a gas at room temperature that boils at 240 K (−33°C), but the new compound is now a solid at room temperature with a melting point of 306 K (+33°C). As such, it is the highest-melting compound with the low molecular mass of 33.0298 g/mol. This change in physical properties is due to the extensive formation of hydrogen bonds. Hydrogen bonds can be measured by spectroscopic methods (discussed later).

The boiling point of HA is 343 K (70°C) at a reduced pressure of 60 mm Hg. The distillation of HA is a **hazardous** operation because the vapors **and the liquid** may detonate [36]. Hydroxylamine cannot be distilled at atmospheric pressure. Physical properties of hydroxylamine free base are summarized in Table 1.

Table 1: Physical properties of hydroxylamine free base.

Property	At	SI units	Other units	References
Melting point		306.2 K	33.05°C	[36]
Melting point		305.2 K	32.05°C	[36]
Boiling point	22 mm Hg	329–330 K	56–57°C	[36]
Boiling point	60 mm Hg	343 K	70°C	[36]
Vapor pressure	0°C	35.9 Pa	0.27 mm Hg	[37]
Vapor pressure	32°C (melting point)	704 Pa	5.3 mm Hg	[37]
Vapor pressure	47.2°C	1.33 kPa	10 mm Hg	[37]
Vapor pressure	64.6°C	5.3 kPa	40 mm Hg	[37]
Vapor pressure	77.5°C	13.3 kPa	100 mm Hg	[37]
Density, solid	0°C		1.2255 g/mL	[36]
Density, liquid	33°C		1.204 g/mL	[36]

The vapor pressure of hydroxylamine in the range from 261 to 280 K (−12 to +7°C) can be expressed by the equation (Back and Betts [37])

$$\log p = 11.7102 - \frac{3352.6}{T}$$

where p is the vapor pressure in mm Hg and T is the temperature in kelvin. Vapor density measurements showed that NH_2OH vapor consists of single molecules (no association of binary or multiple clusters in the vapor space) at 36 Pa (0.27 mm Hg) and 298 K (25°C).

1.2.2 Optical Properties of Hydroxylamine Free Base

1.2.2.1 Absorption Spectra of Hydroxylamine Free Base

The absorption spectra of hydroxylamine free base are of interest as a means to analyze HA and HA salt solutions and to determine its molecular structure. Thermodynamic data needed for rocket performance calculations with HA and its salts are derived from spectroscopic data. Attempts have been made to ignite HAN-based propellants with lasers, and before one can select a laser for this task, one must know the absorption spectra of the compound that needs to be ignited.

Based on absorption spectra in the gaseous and solid states in the range 1.5–25 μ , it was concluded that the free base NH_2OH molecule is symmetrical and that *cis* and *trans* forms coexist [38]. The infrared (IR) spectrum of HA vapor is shown in Figure 1. The N–H and N–O bands were recorded at high resolution, and because NH_2OH is a relatively simple molecule, it was possible to assign bonds and types of vibrations to all of the bands observed. The thermodynamic functions of HA vapor could be derived from the IR absorptions. The same paper also contains an IR spectrum of solid hydroxylamine. Once the absorption bands of the free base hydroxylamine are known, it is also easier to assign absorption bands in HAN and other hydroxylammonium salts.

Figure 1: Infrared spectrum of hydroxylamine vapor. (Republished from [38], with permission of © 1952 Canadian Science Publishing; permission conveyed through Copyright Clearance Center, Inc.)

The infrared spectra of thin films of solid H_2NOH and D_2NOD were obtained at 195 and 83 K (–78 and –190 °C) in the region 4000–500 cm^{-1} [39]. Two distinct types of spectra resulted, depending on whether the films were formed at 195 K (–78 °C) or at 83 K (–190 °C). The spectra obtained when the films were formed at 83 K were characterized by broad overlapping bands; those formed at 195 K gave much narrower bands, some of them splitting into two or more distinct components. The latter type of spectrum is representative of the stable crystalline form at low temperature. This spectrum could not be correlated with a postulated ammonia oxide isomeric form of hydroxylamine, $\text{H}_3\text{N}=\text{O}$. Satisfactory vibrational assignments could be made for a model with symme-

try of the point group C_3 , H_2NOH . If *cis*- and *trans*-rotational isomers coexist in the solid, they must possess very nearly the same potential energy or at least a high potential barrier between them. The O—H stretching vibration in the solid was found at a very low frequency, 2867 cm^{-1} , indicating a very strong hydrogen-type bond with an energy of about 54.4 kJ/mol (13 kcal/mol).

Infrared spectra of HA trapped in a matrix of solid nitrogen or solid argon were very helpful for studying the role of hydrogen bonding in forming HA dimers in crystals, melts, solutions, and vapors [40]. Absorption bands were assigned to fundamental vibrations based on the isotope effect in deuterated HA [41]. Photolysis of the $NH_3\text{-}O_3$ complex, formed by reagent co-deposition with excess argon at 10–14 K, gave hydroxylamine as the sole product. Fundamental frequencies were obtained for hydroxylamine isotopes by using deuterium or ^{15}N -enriched NH_3 or ^{18}O -enriched O_3 precursors. Normal isotopic hydroxylamine and both fully and partially deuterated hydroxylamine were also produced in high yields from the thermal decomposition of the tertiary hydroxylammonium phosphate salt, $(NH_3OH)_3PO_4$. All of the fundamental vibrations except the NH_2 rocking were observed for normal isotopic hydroxylamine. The experimental force field of hydroxylamine was constructed from the IR data, and it indicated that the (unobserved) NH_2 rocking occurs in the 1300 cm^{-1} region, as has been predicted by *ab initio* calculations.

IR-optical double resonance studies of the $7\nu_{OH}$ level of hydroxylamine observed spectral features 14 cm^{-1} wide in the vibrational overtone spectra of rotationally selected hydroxylamine [42]. The vapor was flowed through a sample cell at $50\text{ mTorr}=6.6\text{ mPa}$ and was excited with two lasers operating at different wavelengths. The $7\nu_{OH}$ level of NH_2OH is above the N—O dissociation threshold; the finite lifetime of the molecule will broaden the vibrational overtone transitions.

Substitution of the hydrogen in water by various ligands with increasing electron affinity causes shifts in the IR spectra wavelengths and intensities [43]. The atomic polar tensors of the H atom for ROH molecules where $R = H, CH_3, NH_2, HO$, and F, were calculated by the *ab initio* method using the 4–31G basis set. The results were interpreted in terms of the charge, charge flux, atomic dipole flux, and homopolar dipole flux contributions.

The UV spectrum of HA starts at 255 nm and shows a first maximum at 182.5 nm [44]. A minimum at 170 nm is followed by increasing absorption toward shorter wavelength. It may be difficult to record UV spectra of HA because at the shorter wavelength the sample starts decomposing while its spectrum is being recorded. One has to maintain a flow of fresh vapor through the sample cell in order to avoid interference from decomposition products. Nitrous oxide is the main decomposition product, and it is already forming while the spectrum is being recorded. The absorption maximum at 182.5 nm probably corresponds to the dissociative excitation of the lowest excited singlet state. A second dissociative process becomes dominant at wavelengths shorter than 170 nm.

1.2.3 Thermodynamic Properties of Hydroxylamine Free Base

The enthalpy of formation of HA free base is important for calculating the potential energy release in accidental explosions of this chemical and for calculating the enthalpy of formation of HAN if it is made by neutralization of HA free base with nitric acid. Thermodynamic properties of hydroxylamine free base are summarized in Table 2.

Table 2: Thermodynamic properties of hydroxylamine free base.

Property	At	SI units	Other units	References
Enthalpy of formation, solid	298 K	-106.7 kJ/mol	-25.5 kcal/mol	[45]
Enthalpy of formation, vapor	298 K	-47.7 ± 4.6 kJ/mol	-11.4 ± 1.1 kcal/mol	[46]
Enthalpy of formation, vapor	298 K	-42.26 kJ/mol	-10.1 ± 0.3 kcal/mol	[47]
Enthalpy of formation, vapor	298 K	-42.68 kJ/mol	-10.2 kcal/mol	[48]
Heat of vaporization	305 K	47.7 kJ/mol	11.4 kcal/mol	[49]
Heat of vaporization		61 kJ/mol	14.6 kcal/mol	[50]
Enthalpy of sublimation	273 to 305 K	64.18 kJ/mol	15.34 kcal/mol	[49]
Enthalpy of sublimation		64 kJ/mol	15.3 kcal/mol	[50]
Heat capacity of vapor	298 K	$46.7 \text{ J K}^{-1} \text{ mol}^{-1}$	$11.17 \text{ cal } ^\circ\text{C}^{-1} \text{ mol}^{-1}$	[51]
Heat of fusion	305 K	16.48 kJ/mol	3.94 kcal/mol	[49]
Entropy of sublimation	273 to 305 K	$169 \text{ J K}^{-1} \text{ mol}^{-1}$	$40.4 \text{ cal } ^\circ\text{C}^{-1} \text{ mol}^{-1}$	[49]

Actually, HA is a solid at 298 K, but the samples used by early investigators probably were not completely water-free and thus they may have been liquid at 298 K.

Based on a set of *ab initio* calculations, an estimated value of -47.7 ± 4.6 kJ/mol (-11.4 ± 1.1 kcal/mol) for the gaseous HA enthalpy of formation at 101 kPa and 298.17 K was reported [46].

Coupled-cluster *ab initio* calculations through non-iterative triple excitations were used to compute optimized structures, harmonic vibrational frequencies, atomization energies at 0 K, and heats of formation at 298 K for hydroxylamine (NH_2OH) and three related compounds (NH_3 , HNO , and H_2O_2) [47]. The use of basis sets as large as augmented sextuple- ζ resulted in small extrapolations to the complete basis set limit in order to achieve acceptable accuracy (± 1 kcal/mol) in the thermodynamic properties. Excellent agreement with experiments was found for the heats of formation of NH_3 , HNO , and H_2O_2 . For NH_2OH , the best current estimate of the heat of formation at 298 K is -42.26 ± 1.2 kJ/mol (-10.1 ± 0.3 kcal/mol), which falls roughly midway between two experimental values at -50.2 ± 10 kJ/mol (-12.0 ± 2.4 kcal/mol) and -33.0 ± 6.3 kJ/mol (-7.9 ± 1.5 kcal/mol). Other sources [48] give the enthalpy of formation of the vapor as -42.68 kJ/mol = -10.2 kcal/mol. Hydroxylamine is a weak base with a $\text{p}K_{\text{b}}$ of 8 (Table 3).

Table 3: Dissociation properties of hydroxylamine free base.

Property	At	SI units	Other units	References
Dissociation constant	293 K	1.07×10^{-8}		[36]
Dielectric constant		77.63–77.85		[36]
Proton affinity			211 kcal/mol	[36]
pK_a (NH_3OH^+)	293 K	6.04		[52]
pK_b	293 K	8.13		[52]

Because H_2NOH is a relatively simple polyatomic molecule, it has been used for many model calculations in comparison to isoelectronic or similar molecules such as HOOH or H_2NNH_2 . For instance, calculations of chemical interactions give rotational energy profiles and test the rules of additivity and the role of bond–bond, bond–lone pair, and lone-pair–lone-pair interactions [53]. From these calculations, one can predict the enthalpy of formation of the molecule in the vapor phase.

1.2.4 Molecular Structure of Hydroxylamine Free Base

Hydroxylamine is derived from ammonia by replacing one of the hydrogens in the molecule by a hydroxyl group (Figure 2).

**Figure 2:** Molecular structure of hydroxylamine free base

The unique physical and chemical properties of hydroxylamine and its derivatives can be explained through its molecular structure and arrangement of atoms in the molecule. The bond energies of the N–O and N–H bonds are a key parameter in evaluating the stability and the potential explosivity of this molecule.

Based on absorption spectra in the gaseous and solid states in the range 1.5–25 μ , it was concluded that the molecule is symmetrical, belongs to point group C_s , and that *cis* and *trans* forms coexist [54]. At room temperature, no *cis* isomer is observed. Force constants, moments of inertia, rotational constants, and molecular parameters have been evaluated. Thermodynamic functions of the gaseous substance were calculated between 298.16 and 1200 K. The N–O distance was found to be 1.46 Å, and the O–H and N–H distances have nearly the same values as those in water and NH_3 , respectively. The O–H bond with 1.06 Å is slightly longer than in the free radical and lies in the plane of the C_s symmetry.

Microwave spectroscopy and electron diffraction studies have established the *trans* equilibrium structure of NH_2OH belonging to the C_s group, as illustrated in Figure 3.

Figure 3: Hydroxylamine equilibrium geometry. (Based on data from [55].)

The best experimentally determined values for the N—O bond length in hydroxylamine and its N-protonated form are, respectively, 1.453(3) and 1.411(2) Å, the latter being derived from a redetermination of the crystal structure of hydroxylammonium chloride [56]. The data are in good agreement with those from *ab initio* molecular orbital (MO) calculations reported in the literature. The chloride salt crystallizes in space group $P2_1/n$, with $a = 6.954(2)$, $b = 5.943(1)$, $c = 7.286(2)$ Å, $\beta = 114.12(2)^\circ$, and $Z = 4$.

The N—O bond dissociation energy of hydroxylamine was calculated at the level of CCSD(T)/6-31G + (d,p)//MP2/6-31G + (d,p) to be approximately 251 kJ/mol (60 kcal/mol), which suggests that the N—O bond is too strong at ambient temperature to be broken at a significant rate. This number is in good agreement with earlier estimates of 256.5 kJ/mol (61.3 kcal/mol) by Back and Betts [37]. The most likely decomposition pathway was proposed to be the bimolecular isomerization of hydroxylamine into ammonia oxide. Water is a catalyst for the isomerization of HA to ammonia oxide. The activation barrier for this reaction in the gas phase was calculated to be about 108.8 kJ/mol (26 kcal/mol) above the hydroxylamine bimolecular complex, and this reaction in aqueous solution is slightly exothermic, with an energy barrier of only 67 kJ/mol (16 kcal/mol).

A Monte Carlo simulation of liquid hydroxylamine gave theoretical values for the heat of sublimation (64 kJ/mol = 15.3 kcal/mol), the heat of vaporization (61 kJ/mol = 14.6 kcal/mol), the dipole moment of 0.59, and the dielectric constant (predicted for HA 77.7, compared to that predicted for water 78.5) [50].

Using the quantum mechanical software Gaussian 03, HA bimolecular or water-catalyzed HA isomerization to ammonia oxide in aqueous solution was identified as a possible decomposition pathway [57]. With the improvement of computer resources and computational chemistry, molecular simulation has become a powerful and reli-

able tool to complement and guide experimental thermal stability testing. Ammonia oxide is very unstable but survives long enough to play a role in hydroxylamine decomposition and ammonia oxidation [58].

Quantum mechanical calculations were carried out in an effort to predict the enthalpy of formation and bond energies in the hydroxylamine molecule and its proton affinity [59]. Similar calculations were performed to predict the instability of the molecule and explain its explosive behavior.

Hydroxylamine, hydrazine, hydrogen peroxide, methylamine, and methanol all share the same dumbbell shape of the molecule backbone, and calculations of the bond energies and hindrances to free rotation will reveal why some of the molecules will autodecompose and others will not [60]. An energy decomposition scheme in terms of quasi-classical, interference, and charge transfer interactions between non-orthogonal, strictly local molecular orbitals (NOLMOs) was applied to the study of the barriers to internal rotation. It was found that the barriers in these molecules essentially arise from a combination of a number of predominant quasi-classical and interference effects.

1.2.4.1 Hydrogen Bonding in Hydroxylamine Free Base

Hydroxylamine free base has the highest melting point, 306 K (33 °C), of any chemical compound with the same molecular mass. Molecules with similar molecular masses are either liquids or even gases at the same temperature. The reason for the exceptional behavior of HA and many of its salts is the strong hydrogen bonding between the hydrogen atoms of the $\text{H}_2\text{N}-$ group and its neighboring O and N atoms. Because these intermolecular forces affect the physical properties and energy content of HA and its salts, they need to be discussed here in a little more detail.

1.2.4.2 Hydrogen Bonding in Anhydrous Hydroxylamine Free Base

The first step of association of HA molecules leads to formation of dimers (also called homodimers), which may exist in the crystal structure of solid HA, in melts, in solution, or in the vapor phase. The dimerization energies and IR band-wave numbers of dimers of HA were calculated based on the self-consistent field molecular orbital theory [61]. There are three possible structures: a linear alignment with a C_s symmetry and two cyclic dimers with a C_{2h} symmetry. The cyclic dimers can form either five-membered or six-membered rings:

Five-membered ring dimer

Six-membered ring dimer

Of the three possibilities, the six-membered ring is the most likely structure. Calculations were performed assuming that one of the hydroxyl groups in water is the proton donor and that the lone pair of electrons on the nitrogen is the electron donor. The computed IR spectra of the dimers and complexes showed the red wave number shifts and intensity enhancements of O—H and N—H stretching bands typical for hydrogen bonding. Fundamental vibrations calculated for this structure agreed well with bands assigned in IR spectra of HA trapped in a matrix of solid nitrogen or solid argon [40, 41].

Based on X-ray diffraction (XRD) data, four molecules of hydroxylamine are in an orthorhombic unit cell of symmetry $P2_12_12_1$ with the unit cell dimensions $a = 7.20 \text{ \AA}$, $b = 4.39 \text{ \AA}$, and $c = 4.88 \text{ \AA}$ [62]. The N—O bond length is $1.47 \text{ \AA}$.

1.2.4.3 Hydrogen Bonding in Aqueous Hydroxylamine Free Base Solutions

It is known that ammonia has a strong interaction with water when it is dissolved in water. Similar to ammonia, HA dissolving in water acts as a weak base, and the solution is alkaline. When anhydrous HA dissolves in water, some of the dimers and other clusters are broken up because water molecules arrange themselves between the HA molecules and actively participate in the hydrogen bonding. This is why HA solutions have such a low vapor pressure and are very viscous.

The IR spectra of water and hydroxylamine, co-deposited in solid nitrogen and argon matrices at 17 K, confirmed the predictions of *ab initio* theoretical studies that the monomers interact to form a cyclic hydrogen-bonded complex, stabilized by both $\text{OH}\cdots\text{N}$ and $\text{OH}\cdots\text{O}$ bonds [63]. The experimental wave number shifts were compared with those calculated theoretically, and an encouraging degree of agreement was observed.

Molecular orbital calculations of 1:1 $\text{NH}_2\text{OH}\cdots\text{H}_2\text{O}$ associates were carried out using the 6-31G** basis set [64]. The first question was how the formation of the adduct would affect the IR spectra of either HA or the water. It was possible to predict the vibrational wave numbers of H_2NOH and its adduct with a fair degree of accuracy. The most stable structure of the adduct is a five-membered ring with the free O—H group of the water rotating out of the plane of the ring:

As the result of the adduct formation, the N—O bond length is reduced by 0.5 pm, and the O—H bond length is extended by 0.9 pm. In the water molecule, the H—O—H angle widens by 0.5° .

Hydroxylamine free base forms a similar, but less stable, hydrogen-bonded adduct with anhydrous ammonia [65].

Two analytical pair-potential radial distribution functions for $\text{NH}_2\text{OH}\cdot\text{H}_2\text{O}$ have been derived using 6-31G and 6-31G** basis sets for *ab initio* calculations of the interaction energy surface [66]. The results of *ab initio* calculations, and of Monte Carlo simulations performed with these potentials, proved the importance of the polarization functions in potential construction. The structure of hydration solvent molecules surrounding the NH_2OH was shown to consist of a sphere in which up to 18 water molecules are arranged under the influence of H_2NOH . In general terms, the system structure around NH_2OH appears as a large hydration shell ($R = 4.5\text{--}5.0 \text{ \AA}$) involving an average of 16 or 17 water molecules distributed in two semi-shells, each containing eight water molecules, and being oriented around the O and N atoms of the hydroxylamine molecule. This high coordination number can be attributed to the rather large size of the hydroxylamine molecule and the low stabilization energy of hydrogen-bonded structures. In addition, there are interactions between two neighboring H_2NOH molecules arranging themselves head to tail.

1.3 Chemical Properties of Hydroxylamine

1.3.1 Photolysis and Photodissociation of Hydroxylamine

Photolysis of hydroxylamine and its salts is of interest for the laser ignition of rocket and gun propellants. One of the several ways to entice unstable molecules into decomposition is to create vibrationally excited molecules at one frequency (energy level of the light) and subsequently to excite the vibrationally energized molecule into a dissociative electronic state. From then on, the reaction intermediates and ultimate products can be followed by absorption spectrophotometry or laser-induced fluorescence using less energetic (non-dissociating) spectroscopic probes. Because the initial vibrational excitation can strongly influence the motion of the vibrationally excited molecule on the potential energy surface, this process is called vibrationally mediated photodissociation. It provides more information than a single-shot excitation (one-photon photolysis). In the two-step photodissociation, neither photon has sufficient energy to dissociate the molecule from its vibrational ground state, and even the combined energy of two photons is not enough to reach the electronically excited state. Hydroxylamine is a good candidate for studies of vibrational overtone excitation in vibrationally mediated photodissociation of simple molecules [67]. It has both O—H and N—H stretching vibrations that are acceptable to vibrational overtone excitation. One of the decomposition products is hydroxyl free radical, which can easily be detected by laser-induced fluorescence. The one-photon photolysis of hydroxylamine at 240 nm produces NH_2 and OH.

Ultraviolet (UV) light from a mercury lamp (253.7-nm resonance line) becomes much more effective in causing decomposition of HA if the HA vapor contains a trace of mercury vapor as a sensitizer [68]. The product composition is quite different for the direct photolysis and the mercury-sensitized photolysis. The direct photolysis yields

much hydrogen with some N_2O . The Hg-sensitized photolysis gives mostly ammonia with very little H_2 or N_2O . Both reactions form water.

Photolysis of HA vapor with a laser at 193 nm leads to rapid dissociation [69]. The main dissociation channel leads to $\text{H} + \text{H} + \text{HNO}$, with a quantum yield of greater than one. Another channel leads to excited OH and NH_2 . At 193 nm, close to the first maximum in the UV absorption spectrum, the formation of H atoms via

is by far the most important channel, with the N—O bond dissociation contributing less than 10%.

Photoionization mass spectrometry of NH_2OH and ND_2OD showed that the species observed at $m/e = 31$ are HNO^+ and NOH^+ , and that produced at $m/e = 32$ is H_2NO^+ [70]. From the appearance potentials (photon energy expressed in eV), one can derive the bond energies and dissociation energies of the hydroxylamine molecule.

Hydroxylamine photodissociation can be studied in two ways: **(1)** by direct single-photon dissociation and **(2)** by two-photon vibrationally mediated photodissociation. In the vibrationally mediated photodissociation experiments, hydroxylamine excited in the third or fourth O—H stretch overtone state is photolyzed by a second photon of sufficient energy to dissociate only vibrationally excited molecules. Vibrational overtone spectra for the second, third, and fourth overtones of the O—H stretch were obtained via photoacoustic spectroscopy and simulated to obtain rotational constants and line widths [71]. Strong vibrational coupling arising at an energy between the third and fourth overtones and persisting thereafter led to a sharp increase in line width. Ground-state *ab initio* calculations indicated that Fermi coupling between the O—H stretch and NOH bend is significant. They also showed the presence of a barrier to isomerization to ammonia oxide (NH_3O) near the energy of the fourth overtone.

Single-photon dissociation at 240 nm releases most of the excess energy to relative translation (53%) and NH_2 internal energy (40%), with little to OH internal energy (7%). *Ab initio* calculations of the excited state of hydroxylamine showed a small barrier to dissociation because of an avoided crossing and a change in equilibrium geometry from *trans* to bent upon electronic excitation.

The photodissociation of NH_2OH is a useful tool to study interactions between NH and OH free radicals and the recombination of NH_2 and OH radicals. The photodissociation of hydroxylamine following direct single-photon and vibrationally mediated two-photon excitation below 42000 cm^{-1} showed that in all cases the lowest dissociation channel [$\text{NH}_2(\text{X}^2\text{B}_1) + \text{OH}(\text{X}^2\Pi)$] dominates [55]. Single-photon dissociation at 240 nm releases most of the excess energy into relative translation (53%) and NH_2 internal energy (40%, mostly vibrational). OH carries little internal energy (7%), most of it in the form of rotational excitation. One- and two-dimensional potential functions explain the OH product state distributions observed in different experiments in terms of the geometry relaxation of NH_2OH upon electronic excitation. The formation of OH and NH_2 in their electronic ground states is the main channel of the photodissocia-

tion of hydroxylamine at wavelengths above 240 nm. A presumably small proportion of NH_2 radicals are formed in the first excited state. The NH_2 fragments are produced with significant internal energy, accounting for half of the available energy at 240 nm, most likely in the form of vibrational excitation.

Hydroxylamine is a particularly interesting example for the study of non-adiabatic effects in photodissociation. It has a weak N—O bond, with a bonding energy of about 259 kJ/mol (~62 kcal/mol) that can be broken photochemically:

Conical intersections of two states of the same symmetry are usually considered rare and are not frequently observed. The existence of conical intersections of two states of the same symmetry was investigated for the four lowest electronically excited states of NH_2OH using computational methods based on configuration interaction wave functions [72]. The calculation results indicate the existence of “same-symmetry” conical intersections, which may play a role in the photodissociation of HA:

Although the ground electronic state has C_s symmetry (with two equivalent hydrogens), less symmetrical configurations play a role in NH_2OH photodissociation. Similar effects may take place in photolysis of HAN.

1.3.2 Reactions of Hydroxylamine Free Base

1.3.2.1 Reactions with Inorganic Substances

Alkaline solutions of HA free base autoxidize quite readily when exposed to air [73, 74].

Analytical methods for hydroxylamine free base are discussed in a following chapter describing analytical methods for the most important (for rocket applications) hydroxylammonium salt, hydroxylammonium nitrate. The analytical methods for the free base and for its salts are very similar. Hydroxylamine may act as an acid and form salts with sodium or calcium metal in which the analogs to sodium amide or calcium amide are formed, but these salts are unstable and not well characterized.

NH_2OH reacted with ClO_3F at 203 to 293 K (–70 to +20 °C) in EtOH to form $(\text{NH}_3\text{OH})\text{F}$ and unstable $(\text{NH}_3\text{OH})\text{ClO}_3$. $(\text{NH}_3\text{OH})\text{ClO}_3$ decomposed to $(\text{NH}_3\text{OH})\text{NO}_3$ and ClO_2 [75].

Redox Reactions of Hydroxylamine

Hydroxylamine is a reducing agent. The reducing potential depends on the pH of the solution and is strongest if the solution remains caustic, which would liberate some hydroxylamine as the free base. Redox reactions of hydroxylammonium salts, including HAN, are of interest as analytical methods and for the disposal of surplus HAN. Redox reactions catalyzed by traces of transition metals may be responsible for the

limited storage stability of hydroxylamine free base. The most commonly encountered contaminant metal ion is iron in its bivalent state as Fe^{2+} , which forms complexes with hydroxylamine. The working principle of stabilizers and iron scavengers such as α, α' -dipyridyl is based on formation of such complexes.

A study of the kinetics of redox reactions of hydroxylamine and hydroxylammonium with Fe(III) showed that the results obtained were consistent with a mechanism dependent on the relative iron(III)-to-hydroxylamine concentrations [76, 77]. An excess of iron(III) gave a stoichiometry of 2:1 for the total reaction and N_2O as the oxidation product, whereas at equal amounts or excess of hydroxylamine, the stoichiometry reduced to 1:1 with N_2 as the main product.

Reactions with Acids

Acid–base reactions of hydroxylamine free base with various acids lead to the corresponding hydroxylammonium salts. This is the most straightforward and most versatile method for preparing hydroxylammonium salts (Section 3.2.1), but chemically it is not very exciting (as long as one keeps the solutions cool enough to prevent runaway reactions). The most important reactions of hydroxylamine free base are redox reactions in which the amine is the fuel and an associated anion is the oxidizer. These reactions are intermediate steps in the decomposition of hydroxylammonium salts, HAN in particular. A more detailed discussion of HAN decomposition reactions is offered in Section 1.3.5.

1.3.2.2 Reactions with Nitrous Acid

The reaction of hydroxylamine (hydroxylammonium ion) with nitrous acid is an important step in the decomposition of HAN [78]. The reaction of hydroxylammonium hydrochloride and ^{15}N -enriched sodium nitrite in solution in ^{18}O -enriched water led to formation of equal quantities of $^{14}\text{N}^{15}\text{N}^{16}\text{O}$ and $^{15}\text{N}^{14}\text{N}^{16}\text{O}$. When the same reaction was carried out at a pH of 1, an excess of $^{14}\text{N}^{15}\text{N}^{16}\text{O}$ was produced. In both experiments, the concentration of $^{15}\text{N}^{15}\text{N}^{16}\text{O}$ was accounted for on the basis of the reaction of nitrous acid with hydroxylamine to yield nitrous oxide molecules containing one nitrogen atom from each source. ^{18}O exchange occurred to a greater extent in acidic media, and the double-tagged N_2O so produced was mainly $^{14}\text{N}^{15}\text{N}^{18}\text{O}$ rather than a mixture of the isomers $^{14}\text{N}^{15}\text{N}^{18}\text{O}$ and $^{15}\text{N}^{14}\text{N}^{18}\text{O}$. These observations led to the conclusion that in neutral solutions, most of the nitrous oxide produced is formed by dehydration of a symmetrical intermediate, probably hyponitrous acid ($\text{HO}-\text{N}=\text{N}-\text{OH}$). In acidic media, a competitive dehydration of an unsymmetrical intermediate plays an important role. Mechanisms involving nitroxyl as an intermediate are less likely. Oxygen exchange is acid-catalyzed and occurs exclusively with nitrous acid or with an unsymmetrical intermediate formed in the course of this reaction. Oxygen atoms from either nitrous acid or hydroxylamine appeared in the product nitrous oxide. See also [79, 80].

1.3.2.3 Reactions with Organic Compounds

For reactions of organic compounds with hydroxylamine free base, the most important reactions are those with ketones and aldehydes, leading to ketoximes and aldoximes. These compounds are less soluble and are often used as intermediates in the isolation, identification, and purification of ketones and aldehydes because they can be hydrolyzed to release the pure ketone or aldehyde. In addition, the rearrangement of cyclohexanone oxime to ϵ -caprolactam is an important method for the production of nylon-type polyamides.

1.3.2.4 Proton Affinity of Hydroxylamine and Reverse Dissociation of Hydroxylammonium Salts

Reverse dissociation is part of the hydrolysis of salts in aqueous solution. The pK_b of hydroxylamine is 8.13. There have been investigations trying to explain why the pK of hydroxylamine is so high. It has been attempted to explain this abnormality by the strong hydrogen bonding and ion clustering in concentrated solutions.

1.3.2.5 Basicity Constant of Hydroxylamine Free Base

Hydroxylamine is a weak base and is less caustic than its parent base, ammonia. The proton affinity of hydroxylamine and the basicity constant have been studied extensively (Table 4). This parameter is important for the thermal and long-term storage stability of all propellants based on hydroxylammonium salt solutions because a very small percentage of free base exists in an equilibrium even in an acidic medium, and it may be the reason for lack of storage stability. Thus, if the basicity could be increased by synthesizing HA derivatives, it might lead to more storable propellants.

The pH in a solution of hydroxylamine is determined by

$$\text{pH} = \frac{1}{2}pK_h - \frac{1}{2}\log(Cf_{H^+} - a_{H^+})f_{\text{NH}_3\text{OH}^+}$$

where C is the concentration of NH_2OH , a_{H^+} is the activity of the H^+ ion, and f_{H^+} and $f_{\text{NH}_3\text{OH}^+}$ are the activity coefficients of H^+ and NH_3OH^+ ions [83]. On average, K_h was reported as 1.04×10^{-6} at 298 K. From this, K_a was calculated as $K_a = a_{\text{NH}_3\text{OH}^+}a_{\text{OH}^-}/a_{\text{NH}_2\text{OH}} = 0.97 \times 10^{-8}$, which corresponds to $pK_a = 8.02$, which is quite different from later results.

Table 4: Summary of basicity and acidity constants of hydroxylamine free base.

pK_0	Ionic strength	Remarks	References
6.04	1 M	Spectrophotometric	[52]
6.09		Colorimetric	[81]
5.95		At 298 K, glass electrode	[82]
5.98			[83]

The protolysis of hydroxylamine takes place by the following equilibrium:

The ionization constant for this system is

$$K = \frac{[\text{H}^+][\text{NH}_2\text{OH}]}{[\text{NH}_3\text{OH}^+]}$$

The ionization constants of NH_2OH in aqueous NaClO_4 solutions were determined by potentiometric titration at 288, 293, 298, and 308 K (15, 20, 25, and 35 °C) [82]. The thermodynamic values, pK_0 , of the ionization constant of nitrous acid were obtained by extrapolating the pK values to zero ionic strength. NH_2OH was titrated at four different ionic strengths, 0.04, 0.25, 1.00, and 2.25, with ~0.1M NaOH in NaClO_4 solutions. The pK value follows from

$$pK = \text{pH} - \log \left\{ \frac{(C_B + [\text{H}^+])}{[C - (C_B - [\text{H}^+])]} \right\}$$

where $\text{pH} = -\log [\text{H}^+]$, C_B is the total concentration of the added strong base, and C is the total concentration of the NH_2OH . The pK of NH_2OH depends on the ionic strength, I , of the solution in a linear fashion: $pK = pK_0 + BI$, where K_0 is the thermodynamic ionization constant and B is a constant, both depending on the temperature. The thermodynamic protolysis constant K_0 of NH_2OH depends on the temperature, as in

$$\log K_0 = -\left(\frac{a}{T}\right) - cT + b$$

where the constants a , b , and c for hydroxylamine were calculated by the least-squares method based on the values of pK_0 found by titration and obtained as $a = 2.7757 \times 10^{-3}$, $b = 5.8899$, and $c = 8.4782 \times 10^3$. The values of the $-\log K_0$ found were practically linear in $1/T$ and showed the acid strength of the weaker acid, NH_2OH , to increase more rapidly than that of HNO_2 . The pK_a of hydroxylamine at 298 K was 5.95.

Changes in standard free energies, entropies, enthalpies, and heat capacities of the protolytic reactions of NH_2OH could be calculated once the values of a , b , and c were known. For instance,

$$dH^\circ = 2.303 R(a - cT^2)$$

where $R = 1.9873 \text{ cal K}^{-1} \text{ mol}^{-1}$; dH° is positive, and hence the ionization reactions are endothermic; dH° decreases slightly with increasing temperature; $-\log K_0$ has a minimum value at a certain temperature, $T_{\min.} = (a/c)^{0.5}$. NH_2OH has a $T_{\min.}$ of 572 K at $\log K_{0\min.} = -3.81$, which is in the same temperature range as for H_2O .

1.3.3 Hydroxylamine Free Base as a Ligand in Complexes

Similar to aquo and ammino complexes with water or ammonia as ligands in the hydration (complexation) sphere surrounding metal cations, hydroxylamine free base can form hydroxylammino complexes with many cations [84]. Those involving oxidizing cations (nitrate, perchlorate) are explosive and can potentially be used as propellant ingredients, but they may be too sensitive to be produced in large quantities. The shock sensitivity and thermal stability of these compounds has not yet been measured. In the case of lithium, three or one hydroxylamine fill the solvate sphere, and in the case of earth alkaline metals, the number of NH_2OH ligands can be 6, 3, 2, or 1, depending on the size of the cation and the method of preparation. Starting with complexes containing the highest number of ligands, lower complexes can be obtained by slowly evaporating the volatile ligand under vacuum at temperatures below the explosive ignition temperature. In order to calculate the enthalpy of reaction and the standard enthalpies of formation, the heat of sublimation of solid hydroxylamine had to be known. This number was assumed to be 64.18 kJ/mol (15.34 kcal/mol), and the standard enthalpy of formation of hydroxylamine free base was assumed to be -115 kJ/mol (-27.5 kcal/mol), based on some antiquated measurements. The uncertainties with these numbers are carried over into the subsequent calculations. The enthalpies of the reactions

and the standard enthalpies of formation of a group of hydroxylammino complexes with oxidizing anions X in the solid state were calculated and measured calorimetrically [85, 86]. The results are summarized in Table 5 in comparison to the heats of formation of the metal salts from which they were derived. The data were calculated assuming an enthalpy of formation of -115 kJ/mol (-27.5 kcal/mol) for solid hydroxylamine, which is an antiquated number. It would be of interest to compare the thermal stability of the hydroxylammino complex nitrates and perchlorates to that of HAN and perchlorate. Is the complexation in a sphere of solvation, or is the protonation more effective in stabilizing the otherwise unstable hydroxylamine molecule? The strength of ligands bonding in the sphere of coordination of lithium and alkaline earth-metal perchlorates decreases in the order $\text{N}_2\text{H}_4 > \text{NH}_2\text{OH} > \text{NH}_3 > \text{H}_2\text{O}$. The stability of the complexes also influences their heat of dissolution in water, which was also measured and tabulated (but not displayed here).

Table 5: Standard enthalpies of formation of hydroxylammino complexes and the metal perchlorates from which they are derived.

Formula of complex	Molecular mass	Enthalpy of reaction		ΔH_f , crystalline MX_m		ΔH_f , crystalline $[M(NH_2OH)_n]X_m$	
		kJ/mol	kcal/mol	kJ/mol	kcal/mol	kJ/mol	kcal/mol
$[Li(NH_2OH)_3]ClO_4$	205.48	-72.8	-17.4	-381.2	-91.12	-799.1	-191

1.3.4 Analysis of Hydroxylamine Free Base

For rocket applications it will be relatively rare that one has to analyze hydroxylamine free base, but the analysis of any hydroxylammonium salt can be performed using the same methods by first bringing the sample to an alkaline pH, liberating the free base. There is another section on analysis of hydroxylammonium salts in Section 3.4.4.

Hydroxylamine ($<3 \times 10^{-3}$ mol/L) can be quantified by UV spectrophotometry after reaction with an excess of formaldehyde in a buffered solution at pH 12.2. The absorbance of the formaldoxime produced is measured at 218 nm when hydroxylamine is alone but at 230 nm when monochloramine is present, which may interfere with the analysis [87].

Hydroxylamine can be determined by its oxidation to nitrite with a known excess of bromine [88]. Bromine in acidic medium bleaches the dye methyl red. A known excess of bromine when treated with hydroxylamine is reduced to bromide, and the unreacted bromine is determined using methyl red. The method obeys Beer's law in the range 0–5 μ g of hydroxylamine in an overall aqueous volume of 25 mL. The relative standard deviation is 2.7% ($n = 10$) at 3 μ g of hydroxylamine.

Hydroxylamine in mixtures with other hydroxylamines or hydrazines can be analyzed by first derivatizing the mixture with acetone, extracting the oximes and hydrazones with ether, drying, stripping the solvent, and injecting the extract into a gas chromatograph [89].

1.3.5 Thermal Decomposition of Hydroxylamine Free Base

This is one of two sections in this book on the decomposition of hydroxylamine. This is the one discussing only the mechanisms (which are closely interrelated to the mechanisms of decomposition of HA salts as monopropellants) and thermal decomposition from a more academic point of view. The section following this one discusses the explosive hazards in the production and handling of HA free base. In the wake of several industrial accidents with hydroxylamine free base, the thermal decomposition of hydroxylamine and hydroxylamine solutions has been thoroughly investigated. At this point, there does not seem to be any plan to use hydroxylamine free base as a rocket propellant (and that is for a good reason!). But it may be used as an intermediate in the preparation of hydroxylammonium salts for other monopropellants, and that is one reason why we write here about hydroxylamine free base. For actual experimental decomposition and flame studies with hydroxylamine free base, see a later chapter on monopropellants (*Encyclopedia of Monopropellants*).

The useful life of HAN-based monopropellants is limited by the slow decomposition of HAN, often associated with gas evolution and the potential of overpressurizing a storage tank. One of the proposed mechanisms for HAN decomposition puts the blame of insufficient stability not on HAN but on the small amount of HA free base present in the hydrolysis equilibrium. This is why we included a chapter on the decomposition of HA free base in this book. In order to better understand the decomposition of HAN, we will need to look at the decomposition of HA free base first, and then examine what stabilizing effect (if any) the protonation of HA has. It appears that the presence of even a small amount of HA free base significantly decreases the thermal stability of HAN.

It is best to store pure hydroxylamine free base samples in a refrigerator or freezer. The pure, anhydrous hydroxylamine molecule is not stable at room temperature but decomposes slowly to nitrous oxide, water, and ammonia:

The heat of reaction according to the equation

is 4.3 kJ/g, which is very close to the heat release observed in differential thermal analysis (DTA) and differential scanning calorimetry (DSC) experiments with HA and HA solutions. Another reaction sequence allows for formation of hydrogen

but the energy release of this reaction (between 117 and 133 kJ/mol [28 and 32 kcal/mol], depending on which source of information is trusted) is in disagreement with the exothermicity of HA decomposition under many different conditions (with and without the presence of catalysts).

Additional references describe the complex nature of the HA decomposition reaction system by addressing the possibility of different distinct pathways depending on the pH:

Both of these reactions are exothermic.

Calorimetric data for the thermal decomposition of 50 mass-% hydroxylamine/water (HA) in air, both with and without added stabilizers, were measured in closed cells with an automatic pressure-tracking adiabatic calorimeter (APTAC) [90, 91]. The explosive hazard potential was assessed based on the onset of exotherm temperatures, reaction order, activation energies, pressures of non-condensable products, thermal stability at 373 K (100 °C), and effect of HA storage time on stability. The catalytic effects of carbon steel, stainless steel, stainless steel with silica coating, Inconel, titanium, and titanium with silica coating on the reaction self-heat rates and onset temperatures were examined. In borosilicate glass cells, HA was relatively stable at temperatures up to 406 K (133 °C), where the HA decomposition self-heat rate reached 0.05 °C/min. In borosilicate glass cells, there was no significant difference in the onset temperature of HA thermal decomposition reaction with or without stabilizers. The onset temperatures were 406 K (133 °C) and 409 K (136 °C), respectively. The added stabilizers appeared to reduce HA decomposition rates in glass cells and at ambient temperatures. The tested metals and metal surfaces coated with silica acted as catalysts to lower the onset temperatures and increase the self-heat rates. An older sample without stabilizer stored for more than 5 months exhibited a much more energetic decomposition, with an onset temperature of 340 K (67 °C) and a maximum self-heat rate of 132 K/min (132 °C/min), compared with an onset temperature of 409 K (136 °C) and a maximum self-heat rate of 5 K/min (5 °C/min) for a recently received or “new” sample. In both stainless steel and titanium sample cells, the maximum self-heat rate of the HA with stabilizers was lowered by a factor of ~8 compared to the HA without stabilizers. The overall decomposition reaction was modeled with first-order kinetics and indicated an activation energy of ~121–142 kJ/mol (~29–34 kcal/mol).

In continuation of this work, the thermal stability of several members of the hydroxylamine family was studied using adiabatic calorimetry [92]. The study included aqueous solutions of hydroxylamine free base, hydroxylammonium chloride, hydroxylammonium sulfate, and hydroxylamine-*O*-sulfonic acid of concentrations typically used in industry. The catalytic effect of metal surfaces of stainless steel, carbon steel, and titanium was examined. From all the solutions studied, HA free base was the most reactive, displaying higher maximum temperature, pressure, non-condensable pressure, and shorter delay times to maximum rate. The HA free base maximum heat rate was at least about three times faster than that of the other solutions studied, and the pressure rise rate was about 13 times faster. The decomposition reactions of all samples were catalyzed by stainless steel, but only HA free base was catalyzed

significantly by titanium metal. Solid hydroxylammonium chloride, hydroxylammonium sulfate, and hydroxylamine-*O*-sulfonic acid exhibited some stability but only up to ~333 K (~60 °C). A violent reaction occurred with solid hydroxylammonium sulfate that generated a heating rate of >500 K/min (>500 °C/min) and pressure-rise rate >35.8 MPa/min (>5200 psia/min) before the sample cell was completely destroyed by the generated pressure.

Under adverse conditions, the decomposition of pure HA free base compound can take place with explosive force, as several manufacturers of hydroxylamine free base have, unfortunately, found out the hard way (Section 1.4 below).

The rate of HA decomposition and its reaction pathway is dependent on the presence of acids or other bases [93, 94]. This is of particular interest for the study of the decomposition of HAN and other HA salts. The thermokinetic data, such as onset temperature, heat of reaction, maximum self-heat rate, maximum pressure-rise rate, and non-condensable gas pressure, were compared with those of hydroxylamine solution without added impurities. The study showed that the thermal decomposition behavior of hydroxylamine free base is affected by the presence of acid/base, and mixing of hydroxylamine with acid/base may cause inadvertent thermal decomposition at lower than expected temperatures. One of the postulated intermediates in HA decomposition is its isomer and tautomer, ammonia oxide [58, 95]:

Ammonia oxide, a zwitterionic tautomer of hydroxylamine, has been scrutinized as an intermediate to explain the high reactivity of NH_2OH . Some evidence has shown that ammonia oxide exists in the condensed phase and aqueous solution [96]. Ammonia oxide may play a role not only during decomposition of hydroxylamine but also during synthesis of hydroxylamine by oxidation of ammonia. Thermochemical parameters of ammonia oxide were calculated, under standard conditions, using isodesmic reactions at several theoretical methods and several basis sets in comparison to hydrogen peroxide [97]. The quantum chemistry calculations predict the value of molar enthalpy of formation to be 55.7 ± 2.9 kJ/mol and molar Gibbs energy of formation to be 103.8 ± 2.9 kJ/mol, for gaseous ammonia oxide at 1 atm and 298.15 K. The determined molar entropy and molar heat capacity at constant volume, also at 1 atm and 298 K, are 221.1 ± 0.1 J mol⁻¹ K⁻¹ and 28.9 ± 0.3 J · mol⁻¹ · K⁻¹, respectively.

Hydroxylamine isothermal decomposition measurements were performed in the temperature range of 353–433 K (80–160 °C) using an isothermal calorimeter equipped with a pressure-resistant glass reactor and an APTAC employing glass and titanium cells [98]. Reaction products were identified via UV, high-performance liquid chromatography (HPLC), and ion chromatography. Dilute aqueous solutions of hydroxylamine free base (<50% NH_2OH) and HAN solutions (<18% NH_3OHNO_3) were kept at constant temperature for different lengths of time in closed glass cells in an APTAC at 403, 413, and 413 K (130, 140, and 150 °C) and in a closed titanium cell at 403 K (130 °C). There was no evidence of HA decomposition in a glass cell at 403 K (130 °C) during

the 1200 min of the experiment. At 413 K (140 °C), a measurable rate of decomposition started at approximately 300 min. At 413 K (150 °C), decomposition started faster and resulted in immediate reactor venting. In titanium instead of glass, the HA decomposition reaction developed as soon as the cell was heated to reach the desired temperature of isothermal operation, 403 K (130 °C), and its very rapid pressure rise activated the pressure-relief system.

In the wake of several industrial accidents involving hydroxylamine, several studies were devoted to the effect caused by possible contaminants in the reacting mixtures, such as transition metal ions and, in particular, iron ions.

The thermal behaviors of HA free base, hydroxylammonium chloride, and HAN solutions under redox reaction conditions were investigated using a small-scale reaction calorimeter and UV-visible spectroscopy [99]. Generally the free base was more reactive than its salts. The reactions were triggered by aqueous solutions of transition metals, including Cr^{3+} , Cr^{6+} , Mn^{7+} , Co^{3+} , Co^{2+} , and Cu^{2+} . All exothermic reactions were accompanied by precipitation or a change in the UV-visible spectra. The UV-visible spectra indicated that the transition metals, such as Cr^{6+} and Mn^{7+} , were reduced in solutions of NH_3OHCl or NH_3OHNO_3 . HA as a weak base provided precipitation of hydroxides upon contact with all metals. All metals, except Cr^{3+} , continuously reacted with HA. An induction period was observed for the reaction of HA with Co^{3+} .

In the case of reaction of HA and its salts with iron ions, Fe^{3+} was found to trigger an exothermic reaction, especially in HA [100]. The finding on the effect of iron on the decomposition of 50% HA solution is particularly relevant in the effort to explain the causes of several explosions involving HA solutions where iron contamination was suspected.

The thermal decomposition behavior of 50% HA in contact with iron in the form of iron(III) oxide, ferrous ion, and ferric ion was quite different from that of pure HA solutions [101]. HA in contact with iron ion (Fe^{3+} or Fe^{2+}), even in small concentrations and at ambient temperatures, reacted violently to produce a bubbling, foamy system. A great amount of energy, close to 4 kJ/g, was released in a very short period of time, which resulted in boiling of the reaction mass. The measured heat of reaction for hydroxylamine without iron ion was 3.78 kJ/g. Rust caused heterogeneous iron catalysis of the reaction, which was not as violent as homogeneous iron catalysis, where even 0.0004 mol-% (10 ppm) of iron ion added at room temperature triggered the complete decomposition of hydroxylamine.

The transition-metal-catalyzed oxidation (not only decomposition) of HA has been used to analyze solutions with parts-per-billion (ppb) concentrations of ions by thermometrically measuring the rate of heat evolution that is proportional to the amount of contaminating ions (iron or copper).

The runaway-reaction gaseous decomposition products of 50% HA in the absence of air are H_2 , N_2 , N_2O , NO , and NH_3 , with traces of NO_x possible [102]. The presence or absence of air does not have much effect on the product composition: The gas-phase HA decomposition products under runaway conditions for samples run with and with-

out air were N_2O , N_2 , NO , and H_2 . Ammonia was detected in the liquid condensate. Water may be a reaction product, but because the mixture contained water to start with, its source cannot be determined.

One possible source of ignition of HA during vacuum distillation could be the intrusion of air. However, based on APTAC data, the overall kinetics, onset temperatures, non-condensable pressures, times to maximum rate, heat and pressure rates vs. temperature, and mixture vapor pressures for the experiments in vacuum were similar when compared to the corresponding data for HA decomposition in air [103, 104]. The overall activation energy of $119 \pm 8 \text{ kJ/mol}$ ($29 \pm 2 \text{ kcal/mol}$) is low compared to the 257 kJ/mol (61.3 kcal/mol) required to break the $\text{H}_2\text{N}-\text{OH}$ bond reported in the literature. The availability of oxygen from air did not affect detected runaway decomposition products, which were H_2 , N_2 , N_2O , NO , and NH_3 , for samples run in vacuum or with air in contact with the sample. A heat of reaction ΔH_{rxn} of -117 kJ/mol (-28 kcal/mol) was estimated for the HA decomposition reaction under runaway conditions.

Hydroxylamine thermal decomposition proceeds via a network of parallel and sequential reactions involving short-lived intermediates. The type of intermediates and the rates of their formation and destruction are dependent on the operating conditions of the reactor. One cannot operate with pure hydroxylamine at atmospheric pressure because the reaction would be too fast to be analyzed. One has to use a diluent or operate at reduced pressure. Because of its thermal instability and the high pressures produced by its decomposition, for safety reasons the hydroxylamine sample sizes must be small. Because of the very small samples, the potential analytical techniques that can be employed for the identification and quantification of unstable, and even some stable, intermediates must be very sensitive and rapid. Liquid samples of less than 0.5 mL can be withdrawn from the glass reactor to be further analyzed via UV, HPLC, and ion chromatography. The simultaneous identification and quantification of coexisting ammonia, nitrates, nitrites, and other nitrogen bases is difficult.

The thermal decomposition of hydroxylamine was studied via isothermal and isoperibolic calorimetric measurements in a glass and in a metal reactor [105]. Identification of stable intermediates such as ammonia, nitrates, or nitrites during the course of the reaction did not provide any conclusive results about the reaction mechanism. Calorimetric measurements revealed condition-dependent endothermic and exothermic reaction steps that were consistent with previous results based on computational chemistry. These findings corroborate previously reported theories, according to which the NH_2^- moiety (the formation of which is favored in strongly basic solutions) may trigger runaway reactions.

While most of the previous studies used only dilute solutions of HA with a maximum concentration of 50 mass-%, the following study included work with higher concentrations of HA free base. The thermal decomposition of HA/water solutions was studied based on calorimetric data obtained using DTA, a miniature closed-bomb pressure vessel test (MCPVT), a pressure vessel test (PVT), and a steel

tube test [106, 107]. The exotherm onset temperatures using untreated stainless steel cells were more than 70 K below those measured using a glass apparatus. This implies that the exotherm onset temperature depends on the materials of the sample cells. On the other hand, the heat of reaction did not depend on the materials of the sample cells. The intensity of the thermal decomposition increased greatly when the HA concentration was beyond 80 mass-% in the MCPVT. The thermal decomposition of 70 mass-% HA solutions was very violent in the PVT. In addition, HA/water solutions containing more than 80 mass-% HA could detonate in the steel tube test; 80 mass-% HA was easily detonated by a detonator without RDX booster in the steel tube test.

In addition, the decomposition hazard of HA/water solution by the metal ion and iron powder was investigated in this study. The thermal stability of 85 mass-% HA/water solution with iron ion or iron powder was expressed by the exotherm onset temperature by DTA. The exotherm onset temperatures decreased when the concentration of the iron ion or iron powder increased in the DTA measurements. The reactivity of HA/water solution with metal ions of iron, manganese, nickel, chromium, and copper was examined by measuring the mass loss of HA/water solution after the metal ion was added to it at room temperature. The reactivity of HA/water solution with the iron powder was also studied. Ferrous ion, ferric ion, and iron powder reacted vigorously with HA/water solutions [108]. Ignition was spontaneous when the 0.2 mass-% ferric ion solution was added to 85 mass-% HA/water solution. The decomposition reaction of 85 mass-% HA/water solution with Cu^{2+} was calm compared to that of the iron ion. HA/water solutions did not react with Mn^{2+} , Ni^{2+} , or Cr^{3+} at room temperature.

In a DTA apparatus with both gold-plated sample holder cells and plain stainless steel sample holders, 50% HA solutions showed an onset of exotherm at 339 K (66 °C) in the stainless steel cell and 414 K (141 °C) in the gold-plated cells [109].

Several types of carbon catalyze the decomposition of hydroxylamine free base or hydrazine free base [110]. The hydrazine decomposition involves the formation of the diazene $\text{HN}=\text{NH}$ intermediate. The hydroxylamine decomposition probably involves nitroxyl (HNO) or its dimer as an intermediate. HA decomposition is catalyzed by metals on carbon to give N_2 , NH_3 , N_2O , and hyponitrite in varying proportions depending on the catalyst and conditions. The reaction mechanisms of hydrazine and hydroxylamine decomposition are quite different.

Measurements of the heat of explosion of hydroxylamine free base were performed in a metal reactor, employing 30–80 mL solutions containing 1.4–20 g of pure hydroxylamine free base [111]. The measurements showed that increased concentration or temperature resulted in higher global enthalpies of reaction per unit mass of reactant. At 423 K (150 °C), specific enthalpies as high as 8 kJ per gram of hydroxylamine were measured, although in general they were in the range of 3–5 kJ/g.

Because NH_2OH is formed as an intermediate in the metabolism of nitrate-reducing and ammonia-oxidizing bacteria, it was of interest to study the disproportionation of HA solutions in abiotic, anaerobic media [112]. The catalytic disproportionation of NH_2OH has been studied in anaerobic aqueous solutions at pH 6–9.3 and 298 K (25 °C), with $\text{Na}_3[\text{Fe}(\text{CN})_5\text{NH}_3] \cdot 3\text{H}_2\text{O}$ as a precursor of the catalyst $[\text{FeII}(\text{CN})_5\text{H}_2\text{O}]^{3-}$. The oxidation products are N_2 , N_2O , and NO^+ (bound in the nitroprusside ion, NP), and NH_3 is the reduction product. The yields of $\text{N}_2/\text{N}_2\text{O}$ increased with pH and with the concentration of NH_2OH . An intermediate absorbing at 440 nm was always observed, whose formation and decay depend on the medium conditions. It was identified by UV-visible and ^{15}N nuclear magnetic resonance (NMR) spectroscopies as the diazene-bound $[\text{FeII}(\text{CN})_5\text{N}_2\text{H}_2]^{3-}$ ion.

Several density functional and *ab initio* methods were used in conjunction with several basis sets to theoretically investigate the initial thermal decomposition steps of HA, including both unimolecular and bimolecular reaction pathways [113]. The theoretical investigation showed that simple bond dissociations and unimolecular reactions are unlikely to occur. The energetically favorable and most likely initial step of decomposition pathways was a bimolecular isomerization of hydroxylamine into ammonia oxide with an activation barrier of 104.6 kJ/mol (25 kcal/mol). Solvent effects on the initial decomposition pathways were also studied using water-cluster methods and the polarizable continuum model. In water, the activation barrier of the bimolecular isomerization reaction decreased to 67 kJ/mol (16 kcal/mol). The results indicated that the bimolecular isomerization pathway of hydroxylamine is more favorable in aqueous solutions than in the anhydrous material. The bimolecular nature of this reaction means that more dilute aqueous solution will most likely be more stable.

It is not likely that gold will ever be used as a catalyst, but a combined anion photoelectron spectroscopic study and density functional theory computation of the reaction between a single hydroxylamine molecule and a single gold atomic anion, Au^- , showed that an Au^- anion can activate a hydroxylamine molecule by inserting into its N–O bond [114]. This reaction is facilitated by the presence of two minimum-energy crossing points, i.e., spin flips, along the reaction pathway. Other metal anions may have similar activity.

1.4 Explosive Hazards of Hydroxylamine Free Base

The explosive hazard of hydroxylamine free base has been known for a very long time, and precautions for handling this material have been advised in the literature [115]. Hydroxylamine free base would not be used as a rocket propellant, but it is a very useful intermediate in the preparation of hydroxylammonium salts, which are used as rocket or torpedo propellants.

Despite all precautions, two explosions within a few years of each other occurred during the production of 50% HA solutions by distilling HA under reduced pressure.

On 19 February 1999 at 8:14 P. M., a process vessel containing several hundred pounds of HA exploded at the Concept Sciences, Inc. (CSI) production facility in Hanover Township near Allentown, Pennsylvania (Figure 4). Employees were distilling an aqueous solution of HA and potassium sulfate, the first commercial batch to be processed at CSI's new facility. After the distillation process was shut down, the HA in the process tank and associated piping explosively decomposed, most likely due to high concentration and temperature. Four CSI employees and a manager of an adjacent business were killed. Two CSI employees survived the blast with moderate to serious injuries. Four people in nearby buildings were injured. Six firefighters and two security guards suffered minor injuries during emergency response efforts. The production facility was extensively damaged. The force of the explosion produced a crater 4 feet deep and approximately 18 feet in diameter in the floor of the CSI plant. The Federal Emergency Management Agency/U.S. Fire Administration Accident Investigation Board has issued a detailed accident investigation report on this event [116]; also [117]. Immediately prior to the accident that destroyed the CSI plant, the final step in their routine production of HA from hydroxylamine sulfate was a vacuum distillation at 323 K (50 °C), which is well below the temperatures for significant decomposition rates of HA in glass cells reported by various other investigators.

Figure 4: Aerial view of the CSI plant after the explosion. (Photo courtesy of David Lesak, Chief of Lehigh County Hazmat Team – Retired.)

Shortly after the CSI disaster, on 10 June 2000, a factory at Nissin Chemical in Gunma Prefecture in Japan was destroyed by a similar explosion [118–120]. The explosion in a factory where HA/water solutions were manufactured damaged all houses within a radius of 1500 m (4500 ft), and broke many windows. The explosion killed four people and injured 58 others. In a distillation fractionation tower, 50% HA was produced and purified by distilling an 85% HA solution under reduced pressure. The 85% solu-

tion was not a commercial product and existed only as a process stream at this factory. A vessel containing the 85% HA solution was completely destroyed by the explosion. The post-accident investigation concluded that the initial detonation occurred in the 750–800 L of 85% HA solution and the piping leading to and from the reboiler.

In the wake of these two back-to-back explosions, the chemical industry worldwide scrambled to develop a safer process and build replacement production facilities. A quantitative risk assessment is useful for analyzing what went wrong and for developing a safer process if facilities are to be repaired and rebuilt [36].

Because of the explosion hazard and transportation safety restrictions, hydroxylamine free base is available commercially only as a 50 mass-% solution (with a proprietary stabilizer). A common abbreviation for this chemical product is FH-50 (free hydroxylamine–50% solution). It is widely used in the semiconductor integrated circuit industry to remove photoresist masks without leaving any residues. See also [121, 122].

1.5 Experimental Studies on HA as an Energetic Substance

In studying the detonation behavior and as part of the accident investigation, samples containing various concentrations of HA were placed in glass or polyethylene cylinders inside a steel tube and subjected to confined detonability tests [109]. The sample size was either 40 mL in a 25-mm–inner diameter (ID), 200-mm–long glass tube or 980 mL in a 50-mm–diameter, 500-mm–long polyethylene bag in a steel tube. The initiation was with RDX charges or, in one case, with a blasting cap without a booster charge. When detonation occurred, the steel tube was fragmented into six or more pieces. The results are summarized in Table 6.

Table 6: Detonability of hydroxylamine free base solutions

NH ₂ OH concentration, mass-%	Ignition method	Result
90	Detonator + 10 g RDX	Detonation
85	Detonator alone, no RDX	Detonation
85	Detonator + 2 g RDX	Detonation
80	Detonator + 10 g RDX	Detonation
70	Detonator + 10 g RDX	No detonation
50	Detonator + 50 g RDX	No detonation
0 (blank test)	Detonator + 10 g RDX	No detonation

Data source: [109]

As of 2016, FH-50 was available from BASF (Germany), Hangzhou Dayangchem Co. Ltd. (China), and CellMark AB (Sweden), among others. The same three companies also offered HAN solutions.

1.5.1 Theoretical Studies on HA as an Energetic Substance

Several publications describing computational chemistry studies of the molecular structure of the H_2NOH molecule can serve as a base for subsequent hazard analysis and were described in Section 1.2.4. Once the enthalpy of formation of an energetic molecule is obtained by either computer models or calorimetric experiments, the data can be plugged into a reactive hazard analysis model such as CHETAH to calculate the explosion pressure.

1.6 Stabilizers for Hydroxylamine Free Base

Commercially used stabilizers for FH-50 are usually not identified on the product label. That is deplorable because if the HA solution is to be used in making hydroxylammonium salts for monopropellants, the stabilizers are carried over into the salt solution and may act as catalyst poisons. There are numerous stabilizers for HA described in the patent literature, including the trisodium salt of *N*-hydroxyethyl-ethylenediaminetriacetic acid; the tetrasodium salt of ethylenediaminetetraacetic acid; polyvinylpyrrolidone and poly-*N*-vinyl-5-ethyl-oxalidinone [3]; and pyridine or pyridone salts, such as the sodium salt of 2-hydroxypyridine-*N*-oxide, 2-hydroxy-4-methoxy-pyridine-*N*-oxide, 1,2-dimethyl-3-hydroxy-pyridine-4-one, 4-methyl-pyridine-*N*-oxide, 6-methyl-pyridine-*N*-oxide, 1-methyl-3-hydroxy-pyridine-2-one; and combinations thereof [123] or complexones [124]. Some of these may also be suitable for stabilization of hydroxylammonium salt solutions. Stabilizers patented by Heitner 1992 are all sulfur compounds [125] and would definitely have to be avoided in monopropellant rocket applications with catalytic reactors.

1.7 Strand Burning of Hydroxylamine Free Base

Hydroxylamine free base solutions containing 74 mass-% NH_2OH were burned in capillary glass tubes of 2 and 4 mm ID at atmospheric pressure [126]. The regression rate was 1 mm/s. The solutions burn with a yellow flame, and ammonia is one of the decomposition products. Nitric oxide NO was not observed.

1.8 Toxicity of Hydroxylamine Free Base

Although free HA base will most likely never be used as a rocket propellant, the toxicity of HA is listed here because it is closely related to that of its salts such as HAN. The toxicity of hydroxylammonium salts is mostly determined by the cation, protonated hydroxylamine free base, and not so much by the anion. Before hydroxylammonium salts are accepted by the propulsion community as “non-toxic” replacements for hy-

drazine, one must examine the toxicity of hydroxylamine-derived compounds to make sure that one does not unwittingly replace one toxic compound with another. The type of toxicity hazard with hydroxylamine and its salts may be different from that of the well-advertised hydrazine toxicity but may represent a toxicity hazard nevertheless. Hydroxylamine is a natural intermediate in the metabolism of ammonia-oxidizing and nitrate-reducing bacteria. So if the bacteria can live with it, it cannot be that toxic.

Toxicity tests are usually conducted in buffered media. Only very rarely will tests be conducted in strongly alkaline media with hydroxylamine free base, which would have pH values near 11. Once the media are buffered, one would have a mixture of free base and its salts. Therefore, it is difficult to separate the discussion of toxicity into that of the free base and that of its salts. In many cases the title of a publication reads “hydroxylamine,” when in fact the test was conducted in a buffered solution with pH near neutral or below, with very little free base in the equilibrium present. There is a substantial overlap between this current chapter and the one on toxicity of HAN, discussed in more detail in Section 3.11.

Although hydroxylamine is a product of normal cellular metabolism, it is also a potent mutagen *in vitro*. However, in spite of this potential, it has not been shown to possess carcinogenic capabilities. In fact, this chemical has demonstrated carcinostatic activity against certain tumors in animals. Of course, the same has also been said about hydrazinium(2+) sulfate. Hydroxylamine has been shown to inactivate or inhibit a number of cellular enzymes and some viruses *in vitro*. It is also a skin irritant and sensitizer. It causes dermatitis and is corrosive to the eyes. Acute and chronic exposures to hydroxylamine have caused methemoglobinemia and sulfhemoglobinemia [127].

1.8.1 Acute Toxicity of Hydroxylamine Free Base

The lethal dose for 50% of the animals tested (LD_{50}) of HA in mice by oral administration is 408–419 mg/kg.

1.8.2 Mutagenicity of Hydroxylamine Free Base

The mutagenicity of hydroxylamine free base and hydroxylammonium salts has been thoroughly investigated. Hydroxylamine free base interferes with deoxyribonucleic acid (DNA) replication by reacting with various amines that are DNA building blocks. Similar activity was expected for some of its salts.

Hydroxylamine free base has been used in the past by biologists to introduce random mutations by switching base pairs from A to G, or from C to T, which is one of the reactions used to identify genes in DNA sequences. This was done in wheat in an effort to breed more productive varieties. It must be assumed that hydroxylammonium salts would exhibit the same mutagenic activities.

The *Drosophila* wing somatic mutation and recombination test was evaluated for its suitability in genotoxicity screening by testing 30 chemicals, including hydroxyl-

amine [128]. Of the two crosses used, the mwh-flr3 cross turned out to be more convenient than the previously used mwh-flr cross. A qualitative evaluation of the genotoxicity of a compound in the wing assay was possible with as few as 1–2 different exposure concentrations.

In order to generate mutants randomly in the *E. coli uncA* gene (encoding the α -sub-unit of F_1 -ATPase), plasmids carrying *uncA* were treated *in vitro* with hydroxylamine [129]. Restriction fragments of the mutated *uncA* gene were then reconstructed into plasmid pDP34, which expresses all of the F_1F_0 structural genes, and the reconstructed mutant plasmids were expressed in a strain carrying a deletion of chromosomal *uncA*. Each of the mutations was characterized by DNA sequencing, growth assays and biochemical assays of membrane preparations.

One of the series of publications on the mutagenicity of hydroxylamine continued for several years and included at least 14 consecutive publications. A group of Russian authors led by Budowsky published a long series of publications covering a span of ten years from 1969 to 1979 dealing with the mechanisms of the mutagenic action of hydroxylamine and *O*-methylhydroxylamine in a variety of assays [130]. The replication of the phage MS2 in the presence of either hydroxylamine or *O*-methylhydroxylamine (mutagenesis *in vivo*) results in an increase in the reversion frequency of two amber mutations in the maturation protein. When acting on the extracellular phage (mutagenesis *in vitro*), the mutagens do not affect the reversion frequency. The most probable mode of mutagenic action of the hydroxylamines on the vegetative MS2 phage involves the enzymic formation of modified precursors and their incorporation into RNA [131]. Hydroxylamine may react with the adenine, uridine, or cytidine, which are part of the RNA molecule [132]. We are referencing here only a few of the more recent examples of those publications, assuming that the reader will have to pick up the remaining 12 publications from the reference list therein.

The cytotoxic and mutagenic properties of hydroxylamine were studied in *Drosophila* over a wide dose range (0.005–1 M) on adult males up to 125 mM and on embryos for higher concentrations [133]. The effects on adults were examined for two HA derivatives: the hydroxamate dihydroxyurea (DHU) and methoxyamine (MOA). HA at high concentrations (≥ 1 M) was tolerated only by the embryonic test system, where it induced cytostatic and cytotoxic effects such as arrested cleavage and embryonic lethality. At a concentration of 1 M, the regression of embryonic survival leading to egg hatchability on time of treatment indicated that the cytotoxic lesions could be an outcome of a single chemical reaction dependent on the HA concentration. HA proved to be mutagenically inactive over the dose range investigated in both the adult and embryonic test systems. Of the tested derivatives of HA, the hydroxamate DHU was also mutagenically inactive, but the oxy ester MOA was decisively effective in the induction of mutations. The molecular basis of the biological activities of HA and its derivatives were interpreted in the light of known chemical reactions of this chemical series with cellular macromolecules.

A total of 133 compounds including hydroxylamine were tested in the micro-screen assay, which is a multi-endpoint assay and utilizes *E. coli* WP2s(λ) instead of *Salmonella typhimurium* [134]. These included 111 compounds that had been tested in the *S. typhimurium* assay and 66 compounds for which both rodent bioassay and *S. typhimurium* assay data were available. Exposure of *E. coli* WP2s(λ) takes place in serial dilutions of the test compound in microtiter wells (250 μ L), followed by sampling from wells in which growth has occurred (i.e., those where cytotoxicity has not killed the viable material). Although a number of different endpoints can be measured, only the prophage induction endpoint has been extensively tested. The concordance for the microscreen assay and the *S. typhimurium* assay was good (71%). For this group of compounds, the sensitivity of the microscreen assay in detecting carcinogens was 76%, compared with 58% for the *S. typhimurium* assay. However, the *S. typhimurium* assay was somewhat more specific (69%) compared with the microscreen (56%).

Here we are mostly concerned about the potential mutagenicity and carcinogenicity of rocket propellant ingredients such as hydroxylamine and its salts. We were surprised to see a study in which the authors actually suspected that, due to its antioxidant properties, hydroxylamine might be suitable as a preventive treatment against cancer. The effect of administration of hydroxylamine to male and female mice was studied because of reports suggesting an anti-carcinogenic effect and an enhancement of lifespan [135]. In this study, two C3H sub-line breeds were used: the C3H/HeN, which carries a germinal provirus of the mouse mammary tumor virus, and the C3H/HeJ(+), which also carries the milk-transmitted exogenous virus. Lifetime administration of 10 mM HA in the drinking water resulted in a decrease in mammary neoplasm incidence in female C3H/HeN mice but not in female C3H/HeJ(+) mice. Ovarian neoplasms and cysts were common in all groups, indicating ovarian dysfunction, but these were not affected by treatment. The incidences of other cryptogenic neoplasms found in controls in significant numbers, i.e., liver carcinomas, lymphomas, lung adenomas, and adrenal cortex tumors, were only marginally affected in either direction by the treatment. However, an increased incidence of vascular neoplasms of the spleen in hydroxylamine-treated female C3H/HeN mice and vascular neoplasms of the lymph nodes in hydroxylamine-treated male C3H/HeJ(+) mice indicated a sub-line-related action of HA on the reticuloendothelial system. The survival of control mice was 35–58% at 2 years, and this was not increased in either sub line by hydroxylamine, which is interpreted to indicate that this antioxidant does **not** increase lifespan of animals under conditions of maintenance that are adequate for good survival, but it did not kill the mice prematurely, either.

In a study of the bacteriostatic action of hydroxylamine, the results showed that hydroxylamine is bacteriostatic for a number of microorganisms [136]. In some cases, the toxicity may take effect before mutagenicity can be tested. Exposure of cells to high concentrations of hydroxylamine resulted in immediate cessation of DNA, RNA, and protein syntheses. The synthesis of specific proteins (i.e., inducible enzymes) was inhibited to the same extent as total protein synthesis. This also applied to the produc-

tion of constitutive enzymes. DNA isolated from bacteria treated with hydroxylamine did not display altered physicochemical properties, but hydroxylamine prevented the incorporation of amino acids into s-RNA as well as the formation *de novo* of ribosomal, messenger, and s-RNA. The ribosomes as well as the s-RNA prepared from hydroxylamine-treated bacteria were inhibited in their ability to participate in the synthesis of polyphenylalanine.

1.9 Other Occurrences of Hydroxylamine Free Base

Hydroxylamine H_2NOH and its isomer ammonia oxide H_3NO have been postulated as potential short-lived intermediates in the oxidation and combustion of ammonia. Hydroxylamine can form by recombination of hydroxyl and amino radicals

but, of course, that reaction is reversible and is also a path of hydroxylamine decomposition.

Because HAN-based monopropellants are advertised as “green” (environmentally friendly) propellants, they have undergone extensive scrutiny to make sure that they have no such hidden hazards, as some of the hydrazines and perchlorate ion do. When hydrazines and perchlorates were first introduced as rocket propellants, there was less concern about the environmental impact or about occupational hygiene for the handling and disposing of these propellants, or it may be that some of the ramifications of introducing these propellants into rocket test and launch sites were not completely understood. This is why hydroxylamine and its salts were examined before being used as gun or rocket propellants.

Hydroxylamine is an intermediate in many naturally occurring bacterial oxidation and reduction cycles. NH_2OH is an intermediate in biological nitrification. The oxidation of ammonia is mediated by hydroxylamine oxidoreductase. Although this is not a book on microbiology, we thought it would be of interest here to mention the natural occurrence of hydroxylamine and its salts in the biosphere when one has to prepare an environmental impact statement on the use of hydroxylammonium salt in rocket propellants. If we can show that hydroxylamine is a natural intermediate in many nitrogen cycles, then there will be less concern about it accumulating in and damaging the environment. One of the best proofs of this proposition is the fact that some naturally occurring bacteria thrive in a nutrient broth that contains hydroxylamine.

Nitrosomonas europaea, *Nitrosomonas nitrosa*, and *Nitrosococcus oceanus* were successfully grown in a nutrient broth containing hydroxylamine [137]. Significant cell yields were obtained in growth media containing ammonia supplemented with successive small additions of hydroxylamine. The molar growth yield on hydroxylamine, measured as formation of cell protein per unit of substrate oxidized, was found to be approximately twice that on ammonia. In respiration experiments, the oxygen con-

sumption was 1.5 mol O₂ per mol ammonia, and 1.0 mol O₂ per mol hydroxylamine oxidized to nitrite.

Hydroxylamine is an intermediate in the bacterial oxidation of ammonia to nitrite. Cells of *Nitrosomonas europaea* are capable of growing in nutrients with ammonia and hydroxylamine [138]. The molar growth yield on hydroxylamine (4.74 g mol⁻¹ at a growth rate of 0.03 h⁻¹) was higher than expected. Aerobically growing cells of *N. europaea* oxidized ammonia to nitrite with little loss of inorganic nitrogen, while significant inorganic nitrogen losses occurred when cells were grown on mixtures of ammonia and hydroxylamine. In the absence of oxygen, hydroxylamine was oxidized with nitrite as electron acceptor, while nitrous oxide was observed as a by-product. This may be an important natural route to nitrous oxide, a greenhouse gas.

Although the following discussion of the bacterial oxidation of hydroxylamine belongs more in a later chapter on the environmental effects and degradation of hydroxylamine in the environment, the information is presented here because it immediately follows other studies of bacterial interactions that either generate or consume hydroxylamine. As it turns out, there is more hydroxylamine by several orders of magnitude in one form or another already in the environment at any given time than the U.S. Army has ever consumed in its liquid gun propellant development.

Six strains of aqueous heterotrophic bacteria belonging to the genera *Arthrobacter*, *Pseudomonas*, *Aquaspirillum*, and *Macromonas* were found to be capable of hydroxylamine oxidation to nitrites via one or several intermediate products [139]. *A. siderocapsulatus* produced bound hydroxylamine as an intermediate product. The rate of oxidation of that intermediate was lower than that of free hydroxylamine. Hydroxylamine at a concentration greater than 10 mg/L suppressed the bacterial growth (beginning cytotoxicity). *A. siderocapsulatus* and *P. fluorescens* oxidized hydroxylamine. *A. siderocapsulatus* and *P. putida* could not oxidize hydroxylamine when the buffering action of the growth medium decreased.

Hydroxylamine oxidation by *Arthrobacter siderocapsulatus* occurs under aerobic conditions and is intensified in the presence of respiration substrates [140]. The process is specifically inhibited by iron chelating agents and sulfhydryl group reagents. The activity of oxidation rises at the stationary phase of *A. siderocapsulatus* growth parallel to the content of cytochromes B and C, the activity of catalase and peroxidase.

Alcaligenes faecalis var. *nitrificans* was shown to oxidize ammonium via hydroxylation involving electrons directly from the respiration chain [141]. The mechanism of oxidation is similar to that in *Nitrosomonas*, but the source of electrons for hydroxylation is hydroxylamine in the autotrophic bacterium and organic compounds in the heterotrophic bacterium. The enzyme system of *A. faecalis*, which oxidizes ammonium to hydroxylamine, is supposed to be similar to tyrosinase.

An enzyme capable of the oxidation of hydroxylamine to nitrite was isolated from the obligate methylotroph *Methylococcus capsulatus* Bath [142]. The absorption spectra in cell extracts, electron paramagnetic resonance spectra, molecular weight, covalent attachment of heme group to polypeptide, and enzymatic activities suggested

that the enzyme is similar to cytochrome P-460, an iron-containing protein previously observed only in *N. europaea*. The native and sub-unit molecular masses of the *M. capsulatus Bath* protein were 38900 and 16390 Da, respectively; the isoelectric point was 6.98. It is interesting to note that the enzyme has approximately one iron and one copper atom per sub-unit, and these ions also catalyze the autoxidation and decomposition of HA and HAN *in vitro*. Hydroxylamine may even be an intermediate of bacterial activity in the intestinal tract [143]. It was suggested that hydroxylamine may be an intermediate in the oxidative conversion of L-arginine to nitric oxide, a vasorelaxant.

We have a hard time preventing hydroxylamine free base from decomposing in the laboratory under terrestrial conditions. So the last place one would go to look for hydroxylamine would be interstellar space, with its harsh radiation environment. However, the list of complex inorganic and organic molecules detected in interstellar space continues to grow. Ammonia is there. The possibility of NH_2OH to survive under these conditions and its potential to become protonated has been assessed, but the probability of its existing under these conditions is low [144].

1.9.1 Substituted Organic Hydroxylamines

Because hydroxylamine free base is too unstable to be considered as a rocket propellant, its methyl derivatives were at one time evaluated as propellant ingredients. There are two places on the H_2NOH molecule where methyl groups or other organic groups can be attached: One can be attached to the oxygen atom, and up to two can be attached to the nitrogen atom. Several of these derivatives, O-substituted as well as N-substituted alkylhydroxylamines, are known, and a few of them have been evaluated as rocket propellants. Properties of alkyl-substituted hydroxylamines and salts prepared from them are described in Section 6 in this chapter. Hydroxylamine can react at both the nitrogen and the oxygen atoms. For preparation of O-substituted hydroxylamines, the nitrogen atom must be protected to avoid N-alkylation. Monopropellants containing these organic hydroxylamines are described in *Encyclopedia of Monopropellants*.

Hydroxylamine free base is very sensitive to contamination, and several explosions have been blamed on contamination by iron ions. Along the same line, O-methylhydroxylamine and other alkylhydroxylamines are also sensitive to iron(III) contamination [145].

2 Hydroxylammonium Salts

Although hydroxylammonium salts are not typically used as oxidizers in solid propellants, they are discussed here adjacent to ammonium nitrate (AN), ammonium perchlorate (AP), ammonium dinitramide (ADN), and hydrazinium nitroformate (HNF) because in the pure state these compounds are crystalline solids. A few solid propel-

lants have been formulated with solid HAN or hydroxylammonium perchlorate, but they were found to be impractical due to lack of thermal stability. It is also very difficult to obtain hydroxylammonium salts in the water-free state. Therefore, hydroxylammonium salts are used mostly in aqueous solutions.

One of the peculiar properties of hydroxylammonium salts is their extreme hygroscopicity, which makes it difficult to prepare the salts in the pure, dry state. The last traces of water are tenaciously held by these salts, and that makes it difficult to determine their physical properties in the anhydrous state. It takes only a few percent of water to convert hydroxylammonium salt crystals to a viscous liquid. While this may be a hindrance to studying these compounds in the pure, anhydrous state, it is a welcome method for creating liquid oxidizers with relatively high useful oxygen content, low water content, high density, and low freezing points. Compared to the corresponding ammonium salts, hydroxylammonium salts are much more soluble in water than their ammonium counterparts.

The most commonly produced hydroxylammonium salt is hydroxylammonium sulfate, which is the easiest and the most stable form to store and to transport hydroxylamine compounds in the solid state. Much of the hydroxylamine going into production of caprolactam goes through the intermediate state of the sulfate salt and ends up as polyamide elastomers such as nylon.

Hydroxylammonium sulfate can be produced by reduction of aqueous ammonium nitrite with $\text{HSO}_4^-/\text{SO}_2$ as the reductant at 273 K (0 °C). This yields a hydroxylamido-*N,N*-disulfate anion, which can be hydrolyzed to give $(\text{NH}_3\text{OH})_2\text{SO}_4$:

Hydroxylammonium sulfate is an important intermediate in the synthesis of cyclohexanone oxime, which can be converted to caprolactam, which is a precursor in the production of nylon. Initially, it was also the most frequently used intermediate in the production of HAN, but sulfate contamination was a continuing concern, particularly once HAN was beginning to be used as a monopropellant in catalytic thrusters. Sulfate and sulfur would act as catalyst poisons.

The Raschig synthesis of hydroxylamine

is an economical method for producing hydroxylamine for use as an intermediate in the manufacture of oximes. The end product of the Raschig synthesis is an aqueous

solution of hydroxylammonium ions (~1.8 N), ammonium ions (~4.7 N), and hydrogen ions (~1.9 N) balanced by sulfate and, to a minor extent, nitrate ions. The separation of pure hydroxylammonium salts and especially of hydroxylamine free base solutions from the mixtures of salts obtained in the Raschig synthesis presents some difficulties. Fractional crystallization of these mixtures generally fails because of the relatively high proportion of other salts. One method has been to use the Raschig synthesis solution (after neutralization) to prepare the oxime of a volatile ketone:

The resulting ketoxime is separated from the aqueous salt solution by distillation and is subjected to hydrolysis in the presence of a strong acid. This produces a solution of the hydroxylamine salt of the acid and the ketone, which can be recycled:

This method has several drawbacks. The hydrolysis of ketoximes is reversible even at low pH, and continuous removal of liberated ketone is required in order to complete the reaction in the desired direction (and minimize side reactions). Also, hydroxylamine base or salts of hydroxylamine with weak or oxidizing acids cannot be produced directly with this method.

Ion-exchange methods have been used to separate hydroxylamine free base from the reaction mixture [9, 146]. A cation exchange resin can first be loaded with ammonium and will then absorb hydroxylammonium from the product mix. Hydroxylammonium ions in aqueous acidic solutions displace ammonium ions from sulfonic acid resins. In the last step, hydroxylamine liberated by ammonia treatment of the ion-exchange resin in a column elutes later than ionic components present in the resin [8].

Nomenclature. When conducting literature searches, it has been noted that many authors and librarians have misspelled hydroxylammonium nitrate as “hydroxyl ammonium nitrate” in three words. The incorrect name “hydroxylamine nitrate” is also occasionally found in the literature. It is therefore recommended that literature searches be conducted for both or all three spellings.

3 Hydroxylammonium Nitrate

Hydroxylammonium nitrate, also known as hydroxyammonium nitrate, hydroxylamine nitrate, hydroxyazanum nitrate, NH_3OHNO_3 , $\text{N}_2\text{H}_4\text{O}_4$, CAS RN [13465-08-2], HAN, is the most important hydroxylammonium compound for rocket applications. In comparison, the other hydroxylammonium salts have only limited interest, but we list them here for comparison.

Hydroxylammonium nitrate solutions contain an intimate mixture of hydroxylammonium ions, nitrate ions, associated ion pairs, ion clusters, some undissociated HAN, and traces of free hydroxylamine in equilibrium:

In addition to information on solid propellant oxidizers, the properties of the aqueous solutions of these salts are included here for further reference since they are the main reason for the recent popularity of these compounds as liquid oxidizers, and all solid propellant oxidizers start out as aqueous solutions in one point of their lives. Again during demilitarization at end of life and the eventual recycling of ingredients, aqueous solutions of solid propellant oxidizers are an important part of the recycling process. The properties listed in the following chapters are thus not restricted to those of solid compounds, but they also include their aqueous solutions. Concentrated solutions of HAN and its mixtures with other water-soluble oxidizers can be used as liquid oxidizers in bipropellant rocket engines, bipropellant liquid-propellant guns, hybrid rocket engines, and for achieving the complete combustion of fuel-rich torpedo propellant exhaust to minimize the wake signature of torpedoes under water.

3.1 Literature on Hydroxylammonium Nitrate

A good summary of the properties of HAN and HAN-based liquid propellants is contained in a series of conference proceedings published by the Ballistics Research Laboratory entitled “__th Annual Conference on HAN-Based Liquid Propellants.” Five of these conferences were held during the period 1985–1990 [147–149].

3.2 Production of Hydroxylammonium Nitrate

Most rocket propellant chemists will prefer to purchase their ingredients from a reliable chemical supplier and not have to worry about how to manufacture these energetic materials themselves. However, once in a while, it may be difficult to find a chemical with the desired purity or in the necessary quantities, and the propellant chemist may have to make decisions about alternate suppliers and alternate methods of production. In any case, contaminants carried over from various production processes may result in lack of thermal stability or lack of storage stability when a propellant chemist begins to formulate a new propellant. Contaminants (e.g., mercury carried over from electrolytic processes) may make it more difficult to

dispose of process wastes. For most of the chemicals discussed as rocket propellants in this book, a short note about the methods of production will suffice. For HAN and also for ADN, we made an exception and are providing a more detailed description of production methods. Before using any chemical as a rocket propellant, it helps to know how the chemical was made and which contaminants to watch out for. If rocket propellant or liquid gun propellant applications are the only industrial use of an oxidizer, industry may decide to discontinue production if the military consumption of a specific oxidizer suddenly drops below the point where it is economical and profitable to continue to operate a large production facility. In those instances, the rocket propellant chemist will have to search for alternate methods to produce the needed chemical.

The supply situation for HAN in the United States has changed dramatically in both directions during the past 20 years. At the beginning of the 1990s, there was only one commercial source for HAN in the United States, Southwestern Analytical Chemicals in Austin, Texas (currently called Sachem Inc. [150]). The highest concentration initially offered was only 24% (4.8 M) HAN. Under the tradename Tronos 415, a 2-M (18%) HAN solution was offered at one time for printed circuit board processes. This solution was stabilized by an excess of 0.05–0.3% HNO_3 . It was assumed that Sachem used an ion exchange method for its product, which was mostly supplied to the nuclear reactor fuel element reprocessing industry. In 1992, Olin Chemicals brought the first electrolytic reduction HAN production plant on line under a U.S. government contract that supplied HAN for RLPG testing for several years. The HAN produced by the electrolytic reduction of nitric acid is a higher-purity product than HAN produced by metathetical reactions. At the same location, Olin also operated a concentrating plant that produced 13-M HAN. In late 1997, the U.S. Army transferred ownership of the HAN production facility at the Olin Chemicals complex in Charleston, Tennessee, to Olin. Under a previous contract with the Army, Olin had built and operated this HAN plant while the Army explored alternatives to traditional solid gun propellants. Based on proprietary technology developed by Olin in 1984, the plant was initially built to explore the potential use of HAN as a safe liquid propellant for artillery weapons. After the cancellation of the U.S. Army Crusader regenerative liquid propellant gun (RLPG) program, Olin discontinued HAN production at the Charleston plant and, in a company-structure reorganization, spun off the specialties chemicals line (including the hydrazines business) as Arch Chemicals. Arch Chemicals was acquired by Lonza in 2011, the HAN propellants products line was discontinued, and the production facility was dismantled.

Hydroxylammonium nitrate can be produced by several methods, including neutralization of hydroxylamine free base with dilute nitric acid, electrolysis of nitrate ions, catalytic reduction of nitrous oxide, metathetical reactions, and ion exchange reactions. Hydroxylammonium nitrate solutions offered by some suppliers were found to have a high sulfate content, which made it impossible to use this material in mono-propellant reactors with platinum group catalysts.

Most of the methods described here result in only dilute aqueous solutions of HAN. Therefore, the method of concentrating dilute HAN solutions to concentrations that make them useful as rocket propellants is a critical step in developing the overall technology. During the early years when HAN-based propellants were first developed and tested in small quantities, there have been accidents when HAN solutions were heated under vacuum to drive off the water.

When HAN began to be evaluated as an ingredient for liquid monopropellants in rocket engines in the early 1990s, the rocket and space program benefited from the experience that had been gained by the U.S. Army and its contractors in developing HAN-based liquid gun propellants for its RLPG during the preceding two decades. For several years, a new 155-mm self-propelled howitzer (AFAS “Crusader”) was based on this gun concept, and the chemical industry was gearing up to produce HAN-based liquid gun propellants in large quantities.

The Advanced Field Artillery System (AFAS) was conceived as a 155-mm self-propelled howitzer system that was supposed to provide a significant increase in artillery survivability/lethality, mobility, and operational capability and effectiveness through the use and integration of advanced technology in its sub-systems and combat components. For a long time, the baseline AFAS critical technologies and capabilities included an RLPG and XM46 insensitive liquid propellant. The LP cannon promised greater range and lower per-round cost but stretched the AFAS schedule by 2 years or more. Both liquid-propellant AFAS and solid-propellant Crusaders were to have multiple-round simultaneous impact (MRSI) capability.

When the AFAS Crusader switched from liquid propellants to solid propellants (Uni-Charge) in 1994, there was an abundance of unused HAN production capacity that was eventually idled because there were few other uses for this chemical. One of the other commercial uses of HAN was in the reprocessing of spent nuclear reactor fuel rods in the Purex process, where it was used along with hydrazinium nitrate solutions to separate uranium and trans uranium elements, but that process uses only a fraction of the amount of HAN that would have been consumed by a fully fielded AFAS RLPG program. Other countries may still be pursuing liquid propellant guns; see [151].

3.2.1 Production of Hydroxylammonium Nitrate by Neutralization of Hydroxylamine Free Base

The most difficult part of this method is not the neutralization but the preparation of the dilute hydroxylamine free base solution that goes into the process (Section 1.1). The dilute hydroxylamine free base solution can be obtained by a number of processes, many of which are described in patents.

Once hydroxylamine free base solutions started being used for the removal of photomasks on integrated circuits, they became available in the commercial open market from several vendors. It would be easiest to use such commercially available hydroxylamine free base solutions and neutralize them with the acid of choice to make any

hydroxylammonium salt wanted. When using commercially available 50% free base solutions, one must remember that these contain a non-volatile stabilizer that may contaminate the HAN product if the 50% free base solution is used without prior distillation. Distillation of 50% HA free base is a **hazardous** operation. The distillate no longer has the benefit of the stabilizer and will decompose faster than the commercially available HA solution. Stabilizers are usually chelating agents. The exact nature of the stabilizer is proprietary information – it may not even be listed in the Material Safety Data Sheet (MSDS) – but it has been speculated that it might be EDTA, 8-hydroxyquinolin, pyrogallol, or ascorbic acid.

A simple process for the production of concentrated and high-purity HAN has been described in which diluted nitric acid is slowly added to a solution containing excess aqueous hydroxylamine while the resultant mixture is agitated to obtain uniform mixing to avoid locally high concentrations of nitric acid. The batch is cooled to keep the temperature below 333 K (60 °C) [152] or even 323 K (50 °C) [153]. Conversely, addition of hydroxylamine to nitric acid causes spontaneous decomposition of the product HAN, even when the nitric acid has been diluted to less than about 50 mass-%.

A HAN production process patented to Thiokol [154–156] first distills the free base liberated from hydroxylammonium sulfate with alkali under reduced pressure at temperatures below 338 K (65 °C) without alcohol auxiliary fluids to obtain a solution containing 10–50 mass-% hydroxylamine, and then neutralizes the base with 20–70 mass-% HNO_3 at 223–293 K (–50 to 20 °C). The patent claims emphasize that the process is carried out without alcohols. Apparently, earlier processes distilled the free base while the vapor was diluted with a high-boiling alcohol to prevent explosions. Some of the alcohol carried over into the product, which was an undesirable contaminant. Another, older process extracted HAN with butanol, in which it is more soluble than hydroxylammonium sulfate.

A method described in a different patent also distills the free base from caustified hydroxylammonium chloride or sulfate and then neutralizes the distillate with nitric acid [157]. A similar process treats hydroxylammonium sulfate with sodium hydroxide, separates the free base, and neutralizes it with nitric acid in aqueous solution [158].

The easiest way to convert readily available hydroxylammonium sulfate into other, more valuable rocket propellant ingredients is by ion exchange: The first step is to produce a solution of pure hydroxylamine [159], which is then neutralized with the acid of choice (either nitric acid, perchloric acid, or dinitramide) to obtain a solution of the high-performance rocket propellant ingredient in high purity.

Instead of using sodium hydroxide to liberate the free base from a suspension of finely ground $[\text{NH}_3\text{OH}]_2[\text{SO}_4]$ in methanol or ethanol, one can also use ammonia [160] to liberate hydroxylamine free base in an alcoholic solution and then neutralize it with nitric acid or perchloric acid to obtain HAN or HAP.

The other method is to use sodium alkoxides (sodium methoxide or sodium ethoxide) in alcoholic solution as the base to react with finely ground hydroxylammonium sulfate [161]. Once one has a solution of HA free base in ethanol, HAN or HAP can

be obtained by carefully neutralizing this solution with nitric acid or perchloric acid. The excess alcoholic solution of unreacted hydroxylamine may be recycled and used as starting material for the next batch.

If the hydroxylamine free base to be neutralized contains some ammonia contamination, the resulting HAN will be contaminated by ammonium nitrate. The ammonia contamination in the reactant free HA base can be removed by sparging with an inert gas before neutralizing the solution [162].

Commercially available 50% solutions of hydroxylamine free base (FH-50) contain a proprietary stabilizer, most likely an organic complex-forming chelator, which may interfere with intended applications of HAN solutions prepared by neutralization of FH-50 with nitric acid.

Hydroxylammonium nitrate prepared via a neutralization reaction of hydroxylamine free base and nitric acid at different pH levels was analyzed using Fourier-transform infrared spectroscopy (FTIR) and thermogravimetric analysis (TGA) [163]. Based on TGA, the decomposition temperatures of HAN samples synthesized at pH 5–7 were in the range of 393–413 K (120–140 °C), and the sample synthesized at pH 8 decomposed at a decomposition temperature higher than 413 K (140 °C).

3.2.2 Production of Hydroxylammonium Nitrate by Electrolytic Reduction of Nitrate Ions

The most direct method for production of HAN is the electrolytic reduction of nitrate ion in nitric acid solutions:

Possible intermediates in this reaction are nitrite and hyponitrite.

Based on its extensive experience with membrane cells for chlorine and alkali production, Olin Corporation developed an electrolytic HAN process and built a pilot production plant at Charleston, Tennessee, for the large-scale production of HAN. This process initially used a 300-A electrolytic cell with horizontal membrane and opposing mercury pool cathode and produced 3.0 molar HAN at 3.35 kg/d, 77% cathode current efficiency, and 92% yield from nitric acid at 1.5 kA/m². The excess free nitric acid was removed from the product using weak base anion-exchange resins, and the final product contained less than 2.5 ppm transition metals, 0.5 mass-% ammonium nitrate, and less than 0.1 mass-% excess free nitric acid [164–166]. Seventy percent electronic-grade HNO₃ was reduced in a high-hydrogen–overvoltage mercury cathode horizontal membrane cell and produced a 24 mass-% (3M) HAN solution in excess nitric acid [167–170]. This was a continuous process. Each cell had a cathode area of 6 m² and operated at a current density of up to 3 kA/m². Maintenance of the correct nitric acid concentrations in the two electrolyzer compartments was critical to proper operation of the reactor. At low nitric acid concentrations, hydroxylamine would be reduced at the cathode to ammonia, which is undesirable. At high nitric acid concentrations, HAN would be oxidized to NO_x, which is even worse. Either deviation

is undesirable. A mercury cathode was used on top of a conductive plate that was also the top of the cooling compartment. One design entailed the use of additional space for the separate cooling compartment and did not provide for high circulating catholyte flow rates or against the possible loss of the mercury cathode from the cell. The need to employ special precautions to prevent human exposure to mercury and the potential for contamination of the HAN with mercury were disadvantages of the electrochemical process. This process also required more than 2 mols of high-purity nitric acid for each mol of HAN produced, as well as a separate step to remove excess nitric acid before the HAN could be concentrated for use in propellants. Also, the HAN concentration produced electrolytically was limited to about 3.5 molar and required an additional concentration process to make 13-M HAN.

A balance of the nitric acid concentrations between the two compartments was required to allow water transport across the membrane and to maximize the efficiency of the cell. The product leaving the cathode chamber had to contain excess nitric acid. The product leaving the electrolyzer contained typically 25% HAN and 2.8% nitric acid. The excess nitric acid in the product stream could be evaporated or neutralized by addition of free HA or by passing the solution over a cation-exchange resin saturated with hydroxylammonium ions from a hydroxylammonium sulfate solution [171]. A highly acidic ion exchange resin had to be found that was compatible with HAN and HNO_3 . IONAC CFP-110 (Sybron Chemicals) was one of the ion exchange resins that met these requirements. The HAN solution was then concentrated to 81% (13-M) HAN. See also [172].

HAN solutions as produced by electrolytic reduction of nitric acid contained a substantial excess of free nitric acid that had to be removed or neutralized so that it would not adversely affect the stability of the HAN product. One method to neutralize it without introducing a third component was to neutralize it with free hydroxylamine base or at least a solution of HAN containing an excess of free hydroxylamine base [173]. The solution of hydroxylammonium salt containing free hydroxylamine was made by contacting a portion of the solution of the hydroxylammonium salt substantially free of excess acid with a weak base ion exchange resin. This avoided deterioration of the ion exchange resin by contact with free nitric acid. A similar process used a multi-stage electrochemical reactor with an ion exchange membrane in the last stage, loading it electrolytically with hydroxyl ions, which then neutralized the excess free nitric acid [174].

An electrolysis cell with a mediator compartment or coating prevents mixing of anolyte and catholyte during the electrolysis [175]. Selectivity and yield can be improved by forming a film on the intermediate membrane. Film-forming additives are organic polyamines [176]. The nitrate ion is reduced to a hydroxylammonium salt in the presence of a mediator or a film formed by the mediator. The hydroxylammonium salt can be recovered as such or can be electrochemically converted to hydroxylamine free base.

3.2.3 Production of Hydroxylammonium Nitrate by Electrolytic Reduction of Nitric Oxide

Instead of starting with a nitrate (nitric acid) solution, one can pass nitric oxide through a gas diffusion cathode and obtain either HAN or hydroxylamine free base [177, 178]. Intermediates in this reaction are HNO and H_2NO [179]. In one variation of the nitrate reduction process, nitric oxide, NO, is bubbled through the cell, thereby increasing the yield per Joule [180]. Ammonium ion is present as proton donor. The extent of NO reduction decreases with decreasing proton donor concentration because of a lower rate of NO protonation and higher contribution of a competing pathway in which NO^- is converted to N_2O .

Hydroxylamine was produced in a trickle bed cell by passing nitric oxide gas and sulfuric acid catholyte co-currently downward through a cathode bed of tungsten carbide particles [181]. The dependence of hydroxylamine concentration and current efficiency on cathode activity and the particle size, flow rate, composition of gas and catholyte, bed height, reactor temperature, and pressure was quantified, and operating conditions were optimized. Hydroxylamine concentrations of up to 0.18 mol/L were produced at 62% current efficiency in a single pass through a 0.375-m-high cell operated at atmospheric pressure and a current density of 213 A/m^2 . The hydroxylamine concentration increased with cell pressure and gas flow rate and decreased in catholyte flow. It could be raised to 0.4 mol/L by recycling the catholyte for several passes through the system. The process appears to be controlled by mass transfer at current densities of over 400 A/m^2 and by electrochemical reaction below 300 A/m^2 .

The electroreduction of nitric oxide on smooth platinum in aqueous perchloric and sulfuric acid solutions was studied using linear potential sweep and rotating disc electrode techniques [182]. Three potential peaks were observed with linear sweep voltammetry. The first was a well-resolved peak at $E = 0.25 \text{ V}$. Analysis gave a Tafel slope of approximately 0.110 V, which was independent of acid concentration, and a pseudo-first order rate constant that varied linearly with hydrogen ion activity. The results were dependent on electrode reduction pre-treatment and the state of the platinum surface. A second peak at 0.1 V was not well resolved, but evidence was presented suggesting that this peak may be related to nitrogen formation at a zero-oxidation state on a reduced electrode. A third peak at -0.1 V appeared to be a mixed diffusion-adsorption peak associated mainly with ammonia synthesis. The rotating disc electrode experiments supported these conclusions.

A most extraordinary electrochemical method for producing hydroxylamine from nitric oxide and hydrogen does not consume electricity but instead generates electricity in a fuel cell [183]. Hydroxylamine is the reaction product, and electricity is a by-product. This method for the synthesis of hydroxylamine uses a laboratory-scale nitric oxide-hydrogen fuel cell with 3.5-M sulfuric acid electrolyte, nanocrystalline platinum gas-diffusion electrodes, and a proton exchange membrane. Operating conditions are varied and optimized for different voltages and different NO flow rates. The highest current efficiencies of NH_2OH production obtained were above 80% and were

NO flow-rate dependent. The maximum current density of NO reduction was about 5 mA cm^{-2} in the fuel-cell voltage region from 0.2 V down to very low voltages, in which the highest selectivity of hydroxylamine formation was also obtained.

The waste stream from a HAN electrolysis cell may contain traces of mercury that must be removed before the water can be released to surface water bodies. Thus, after hydroxylammonium ion has been destroyed by oxidation with hypochlorite, the excess of hypochlorite must be removed with a reductant such as sodium hydrosulfite before mercury can be precipitated as mercury(II) sulfide by addition of sulfide ion [184].

3.2.4 Production of Hydroxylammonium Nitrate by Catalytic Reduction of Nitric Acid, Nitric Oxide, or Nitrous Oxide

Instead of electrochemical reduction, catalytic reduction in the presence of hydrogen gas is another method for producing HAN. It is interesting to note that HAN and hydroxylamine free base can not only be produced by catalytic reduction of nitrous oxide with hydrogen gas but that nitrous oxide is also one of the intermediates in the decomposition of HAN and hydroxylamine free base. The two compounds are thus closely related.

The first step in the reduction of nitric oxide (NO) to NH_2OH in nitric acid solution follows the reaction

The first step in the reduction of nitrous oxide (N_2O) to NH_2OH in nitric acid solution follows one of the reactions

or

One of the earliest patents for the production of HAN by catalytic reduction of nitric oxide is the BASF patent [185]. BASF at that time was pioneering the production of nylon from ω -caprolactam. An aqueous solution of ~10% HAN was produced by catalytic reduction of nitric oxide with hydrogen in acid solution over a selectively poisoned platinum catalyst at elevated pressure. The $\text{NO} + \text{H}_2$ feed gas has to be diluted with nitrogen to render it less flammable and less explosive. Nitric acid was continuously supplied during the reaction in an amount necessary for the end-concentration of HAN [186]. Using nitric acid instead of sulfuric acid resulted in less ammonia as a by-product.

The platinum catalyst was used as a suspension in sulfuric acid at 1.5 bar and 313 K (40 °C) in a six-stage reactor, and the emerging mixture of hydroxylammonium sulfate, ammonium sulfate, and catalyst was filtered off before processing the hydroxylammo-

nium salt solution obtained as the filtrate. It was important to recover the expensive platinum on graphite catalyst by redissolving the filter cake and allowing the catalyst to settle so it could be reused [187]. Filtration and sedimentation are very slow processes. In one version of the process, 13% of the nitric oxide was converted to nitrous oxide, an undesirable by-product.

Another patent describes a process for preparing hydroxylammonium salts through catalytic reduction of nitrate ions in an acid (pH 1–4) medium in the presence of a palladium and/or platinum catalyst supported on a carrier in which at least 0.00025 mmol halogen ions are present per m² of palladium and/or platinum area [188]. The hydrogen pressure is between 0.5 and 2 MPa.

In many instances [189, 190] the dilute HAN solution is not isolated as such but is directly reacted with cyclohexanone to produce cyclohexanone oxime for later conversion to ω -caprolactam and polyamides like nylon.

3.2.5 Production of Hydroxylammonium Nitrate by Metathetical Reactions

Hydroxylammonium sulfate is a good starting point for the synthesis of other hydroxylammonium salts because it is available in large quantities as an industrial commodity commonly used for the synthesis of nylon and similar polyamide polymers. It is possible to convert hydroxylammonium sulfate to HAN by a metathetical reaction or by ion exchange. Metathetical reactions work only if it is possible to shift the equilibrium in the desired direction by forming and precipitating an insoluble salt. Thus, HAN can be formed by reaction of barium nitrate with hydroxylammonium sulfate, where the barium sulfate precipitates as sparsely soluble white precipitate:

There is concern about contamination of the product by barium ions and sulfate. The precipitate is so fine that normal filtration and washing are practically impossible, and settling is extremely slow, usually taking 8–16 h.

In a variation of this process that uses less water, a hydroxylammonium salt is slowly added to a well-agitated saturated slurry of either barium nitrate or barium perchlorate [191]. The agitation must be sufficiently vigorous so as to ensure that the hydroxylammonium salt goes into solution and reacts with the dissolved barium salt and does not come into direct contact with the slurried barium salt. Should this undesirable direct contact occur, the soluble salt will receive an insoluble coating, and the reaction will be prematurely curtailed.

Another method to remove HAN from the equilibrium

is to extract it with butanol or an ether in which it is quite soluble [192]. Either *n*-butanol or isobutanol is suitable for this application. The HAN is recovered from the organic phase by countercurrent water extraction or solvent evaporation.

In a similar method, the viscous reaction mixture of the two salts in a little water is heated until it is homogeneous, allowed to cool, and extracted with ethanol. The unwanted salts are precipitated from the extract by adding diethyl ether to the solution, filtering, and slowly evaporating the solvents from the filtrate until HAN crystallizes out. The last two steps are repeated several times for purification [193].

Another method to carry out metathetical reactions is to use electric current as the driving force in electrolysis cells separated by semipermeable membranes. Another electrochemical method for the production of HAN is the electrodialytic process [194]. The process may be superior to some previously employed methods such as the cation-exchange process of Wheelwright [195] in some aspects. It can produce HAN with a low free acid content, a high HAN concentration, and a high chemical yield without recycling, and the capacity of the production facility can be varied over a wide range by changing the current density and flow rate – and all of that can be achieved without any deterioration of product quality. These electrodialytic methods are generally applicable to any ionic metathetical reactions of the type

This conversion can be carried out through a double decomposition electrodialytic reaction, e.g., starting with hydroxylamine hydrochloride and nitric acid:

With semi-permeable membranes of high selectivity now available, one can obtain products of high purity. With bipolar membranes, the concept can be extended to water-splitting triple decomposition reactions; e.g., starting with hydroxylammonium chloride and sodium nitrate

and replacing nitric acid with the less expensive sodium nitrate salt. The multi-compartmented cell for the water-splitting triple decomposition reaction consists of bipolar membranes, which can be made by several different methods. A simple and effective method is to fuse together an anion- and a cation-exchange membrane with heat and pressure. In a multi-cell assembly, consisting of repeating sequences of six different cells, a solution of hydroxylammonium chloride is fed into compartment number 2 and a solution of sodium nitrate goes into compartment number 4. When current is passed, the key product HAN is produced in compartment number 3, while the by-products, hydrochloric acid and sodium hydroxide, are produced in compartments 1 and 5, respectively. Each repeating unit of six cells consists of a bipolar membrane, two anion-exchange membranes, two cation-exchange membranes, two feed compartments, and three product compartments. The electrolytes are recirculated, and the product is withdrawn as soon as it achieves the most economical concentration.

The overall current efficiency drops with increasing concentration of HAN in the product cell number 3. Homogeneous membranes (e.g., CMV and AMV) give a much better yield than heterogeneous membranes (e.g., MC 3470 and MA 3475).

3.2.6 Production of Hydroxylammonium Nitrate by Ion Exchange Reactions

Hydroxylammonium sulfate is converted to HAN by passing an aqueous hydroxylammonium sulfate solution through a cation-exchange resin bed that absorbs the hydroxylammonium ion, washing the excess sulfate ion from the resin bed, and eluting the hydroxylamine as HAN with nitric acid [195, 196]. This process does not go through the intermediate step of liberating HA as the free base.

Hydroxylammonium nitrate can be made in an electrodialysis unit that has a tank divided into chambers by cation-exchange membranes, containing an aqueous solution of hydroxylammonium sulfate and a solution of nitric acid in adjacent chambers [197]. An electric potential is applied so that the NH_3OH^+ and H^+ ions pass through the membrane, and the nitric acid is converted to HAN as desired product.

3.2.7 Preparation of Hydroxylammonium Nitrate by Hydrolysis of Oximes

Cyclohexanoneoxime is a major industrial product used in the synthesis of polyamides (nylon). Hydrolysis of cyclohexanone oxime with dilute nitric acid gives solutions of HAN [198]. The effects of the molar ratio of cyclohexanone oxime to nitric acid, the amount of water, the reaction temperature, the reaction time, and the extraction solvent on the hydrolysis reaction were investigated. The results indicate that the conversion of cyclohexanone oxime can reach 62 with 97% selectivity to HAN and 97% selectivity to cyclohexanone under the optimal reaction conditions.

3.2.8 Catalytic Hydroxylamine Production Methods

The catalytic reduction of NO is a convenient route for the production of hydroxylammonium salts:

However, the reaction is not as simple as it seems. In acidic solutions, three competing reactions take place

of which only the second one gives the desired product. The selectivity among the three products depends strongly on the partial pressure of NO in the gas phase. Increasing the partial pressure of NO causes the rates of NH_3OH^+ and NH_4^+ formation to increase, reach a maximum, and finally drop to nil, while the rate of N_2O formation continues to increase all the way. There is only a narrow partial pressure regime (around 0.02 MPa) where NH_3OH^+ and NH_4^+ are produced. Most processes use a platinum catalyst supported on activated carbon, suspended in diluted (<6 N) sulfuric acid. These methods produce hydroxylammonium salts instead of hydroxylamine free base. Of those, the method producing HAN by electrolytic reduction of nitrate ion is the one receiving the most interest and it is discussed in detail in Section 3.2.3.

3.2.9 Production of Hydroxylammonium Nitrate by Oxidation of Ammonia

An integrated process was developed for the synthesis of hydroxylammonium salts with ammonia and hydrogen peroxide as raw materials [199]. This is similar to the process that was aimed at hydroxylamine free base instead of its salts (Section 1.1.4). In this process, hydroxylamine is produced from a combination process of cyclohexanone ammoximation and cyclohexanone oxime hydrolysis, whereby cyclohexanone and its corresponding oxime, which is circulated, act as the “reaction carrier.” Solid hydroxylammonium salts were obtained through the integrated process, which corresponds to an overall yield of 64.2% with respect to ammonia. An intriguing feature of the process is that the reaction carrier, as well as the catalyst employed, can be recycled in the process. This process reminds one of the Produits Chimiques Ugine Kuhlmann (PCUK) process for production of hydrazine hydrate, which also starts with hydrogen peroxide and a ketone as the intermediate. The main objective of these processes was to make cyclohexanone oxime for conversion to caprolactam and polyamides, not to produce hydroxylammonium salts. In this case, both the nylon industry and the rocket propellant makers may benefit from the same invention.

An alternate ammoximation process uses cyclohexanone and ammonium chloride instead of free ammonia as the source of nitrogen and titanium silicalite as catalyst [200]. This new process should now be adapted to the synthesis of HAN instead of cyclohexanone oxime. This process uses a titanium silicalite zeolite with a controlled number of crystal defects as the catalyst [201]. The catalytic mechanisms of titanium species in TS-1 zeolite for the hydroxylamine formation have been investigated using density functional theory. The reaction process for making hydroxylamine can be divided into two steps: **(1)** the H_2O_2 decomposition over the Ti species to produce the peroxo titanium species, and **(2)** the NH_3 oxidation over the generated oxidizing species. The results indicated that defective Ti sites in the TS-1 zeolite are the dominant catalytic sites for H_2O_2 decomposition rather than perfect Ti species, leading to the formation of Ti—OOH species as oxygen-donating intermediates for the NH_3 oxidation reaction. This process can be carried out as a continuous process in a microreactor [202].

3.2.10 Purification of HAN Solutions

The storage life of HAN solutions and propellants prepared therefrom is limited by contaminants introduced inadvertently during their preparation or leached from container materials during storage. The feasibility of removing transition metal contaminants (trace quantities of iron and copper ion) from HAN solutions by cathodic reduction and some non-electrochemical techniques has been experimentally evaluated [203]. A high-mass-transfer packed-bed electrochemical reactor was designed and built for removing the trace metals by cathodic plating. Several bed and electrode materials were evaluated, including lead and amalgamated copper, varying electrode potentials, and solution pH. Although cathodic plating of copper worked quite well with a removal efficiency of 93%, iron was not so easily removed. Lead was unsuitable as a substrate, but amalgamated copper was a candidate substrate material. Both electrochemical and non-electrochemical techniques for removing metal ions as a hydroxide precipitate were investigated. Co-precipitation using alumina as a coagulation agent at a pH of 3.1 seemed to work for iron removal.

HAN prepared by electrolytic reduction of nitric acid by the Olin process may contain traces of mercury as a contaminant. Mercury contamination can be removed by precipitation as mercury sulfide [204, 205].

3.2.11 Concentrating of HAN Solutions

Commercially available 24% HAN solutions can be concentrated in a Rotavapor under vacuum (12 mm Hg) from a bath temperature of 323 K (122°F). This process has been scaled up to a 50-gallon batch process [206]. At room temperature, water will dissolve up to 95 mass-% HAN [207].

One must remember that the storage stability of HAN solutions is improved by maintaining a small, controlled excess of free nitric acid. During distillation, any free nitric acid that may have been in the starting product is lost with the water. The free nitric acid content in the concentrated residue may have to be adjusted again to improve the storage stability of the product. Samples of 92% HAN kept in a thermostatted 338 K (65°C) bath for several days showed a gradually increasing free acid content and fumed off after several days in test.

Concentrated solutions of inorganic hydroxylammonium salts, including HAN, can be safely produced in a continuous process by contact with a semipermeable membrane having a sorption side and a desorption side [208, 209]. The dilute solution is in contact with the sorption side of a membrane, which is substantially permeable to the solvent and impermeable to the solute of the solution. The solvent can flow through the membrane to the desorption side and will then be desorbed by a purge. This process does not require direct heating of the solution and is much safer than distillation methods.

3.2.12 Preparation of Solid Hydroxylammonium Nitrate

Because it is very difficult to remove the last few percent of water from a very concentrated HAN solution, and because the solutions have a tendency to supercool, solid HAN is not often prepared. There are not many applications that would need pure anhydrous HAN. Some investigators needed pure solid HAN to record its spectra and determine crystal structures, but for rocket applications one would hardly ever want to prepare solid HAN.

In one case where solid HAN was prepared, the water was removed by vacuum drying over a **3-month** time period, but the sample still contained some impurities [210]. The impurity level calculated from the change in melting temperature with fraction melted was 0.040 mol fraction. Chemical analysis indicated that the sample contained 0.005 mol fraction HNO_3 and 0.007 mol fraction NH_4NO_3 , with $\text{N}_2\text{H}_5\text{NO}_3$ absent for sure. The remainder of the impurity could have been water, but this is not known for certain.

Few rocket propellant preparations need HAN in the solid state. It is usually very difficult to obtain dry HAN from aqueous solutions. Solid HAN can be obtained by operating in alcoholic instead of aqueous solutions, by slowly adding HNO_3 to an alcoholic solution of hydroxylamine [211]. This procedure forms a HAN precipitate. However, if more HNO_3 is added, the precipitate dissolves before the stoichiometric amount of acid can be added. Therefore, only just-sufficient HNO_3 is added to form a maximum amount of solid HAN precipitate. The solid HAN is then isolated by conventional means (e.g., filtration or centrifugation), possibly preceded by chilling of the solution. The excess alcoholic solution of unreacted hydroxylamine may be recycled and reused as starting material for the next batch. Formation of methyl nitrate must be avoided because methyl nitrate is a sensitive explosive. Another method adds a water-miscible solvent (an alcohol) in which HAN is not soluble to an 80-% aqueous HAN solution, causing the salt to precipitate [212]. This idea should have been no longer patentable in 1997 because it has been described in prior-art open literature.

Solid HAN can be prepared by metathetical reactions of hydroxylammonium chloride with zinc nitrate, silver nitrate, lead(II) nitrate, or chromium(III) nitrate in ethanol, an ethanol/methanol mixture, or diethyl ether, where the HAN precipitated and the metal chloride remained in solution [213]. The purity of the product was verified by ion chromatography. Melting point, DSC traces, and isochoric, isothermal reactor pressure traces of a 90% solution of this product were identical to those of HAN prepared by neutralization of a 50% HA solution with HNO_3 .

A dual-solvent extraction method was used to obtain HAN in solid particulate form [214]. The dehydrated crystals obtained from an aqueous HAN solution were washed with dual organic solvents, including acetone and ethanol.

3.3 Physical Properties of Solid HAN and HAN Solutions

The physical properties of HAN are summarized in Table 7.

Table 7: Physical properties of hydroxylammonium nitrate.

Property	SI units	Other units	References
Molecular mass	96.04 g/mol	10.4123 mol/kg	
Melting point, α -HAN	308.77 ± 0.65 K	35.72 ± 0.65 °C	[215]
Melting point, β -HAN	320.88 ± 1.69 K	47.73 ± 1.69 °C	[215]
Density at 298 K	1.841 g/cm ³		
Enthalpy of formation	−366.5 kJ/mol	−87.6 kcal/mol	[216]

3.3.1 Melting Point of Solid HAN

Literature data for the melting point of pure, anhydrous HAN vary widely because it is extremely difficult to remove the last traces of water, which can cause a strong melting-point depression. Based on a melting endotherm of 2–3 mg HAN samples during DSC, a melting point of 315.4 K (42.2 °C) was reported [217].

Other sources give the melting point of pure HAN as 321 K (48 °C) [218]. With this low a melting point, it would be impractical to attempt to make solid composite propellants with HAN. Gelled HAN-based propellants have been cast into the shape of solid propellant grains instead.

Crystalline HAN exists in two modifications, α -HAN and β -HAN [215]. Measurements by DSC determined that the onset of melting of α -HAN was at 308.77 ± 0.65 K (35.72 ± 0.65 °C), and the onset of melting of β -HAN was at 320.88 ± 1.69 K (47.73 ± 1.69 °C).

3.3.1.1 Freezing Points and Melting Points of Binary Systems

It is very difficult to experimentally determine freezing points of HAN solutions because the solutions supercool and do not give a sharp freezing point. The solutions become more and more viscous and then solidify to a transparent glass. The temperature at which this happens is called the glass transition temperature. It can be determined by measuring other properties (heat capacity) of the mixture while the solidification takes place. The processes taking place during the solidification of HAN solutions are discussed in more detail in the sections on viscosity and molecular structure of HAN solutions, Section 3.3.3 and 3.3.8.2

The HAN/water binary phase diagram is a simple eutectic type with the eutectic at 231.5 K (−41.7 °C) and a HAN mol fraction of 0.281 (mass fraction HAN = 0.676) (Figure 5) [210]. The melting temperature for an impure sample of HAN was 315.9 K (42.7 °C). The melting point corrected to zero impurity was 317.7 ± 1 K (44.5 °C). The enthalpy of fusion of the HAN was determined from the solid and liquid results to be 11 ± 2 kJ/mol.

Figure 5: Freezing-point diagram for the HAN/water system. (Chart created by Schmidt 2016, based on data from [219].)

DSC studies of melting and phase transitions of HAN/water solutions over the range of 123–293 K (–150 to +20 °C) measured in glass ampoules with flat bottoms (Mettler DSC crucibles, in order to avoid interference by corrosion of metal crucibles commonly used in DSC), showed that HAN/water solutions have the properties of dilute aqueous solutions at low HAN concentrations and the properties of molten salts at high HAN concentrations [220]. The molten salt behavior continues to appear at HAN concentrations below 11 M, but it disappears at and below 0.4 M. The glass transition temperatures and the change in heat capacity are summarized in Table 8.

Triethanolammonium nitrate (TEAN)/water solutions behaved very similarly, with an exotherm occurring at 200 K (–73 °C). The data suggest that more than one

Table 8: Glass transition temperatures of HAN solutions.

HAN concentration mol/L	Glass transition, °C		ΔHeat capacity	
	Onset	Complete	Cal g ^{–1} °C ^{–1}	J g ^{–1} K ^{–1}
15.8	–90.1	–84.6	0.264	1.104

crystal form of the salt is obtained, possibly with different numbers of water of hydration.

The solubility of HAN in water at various temperatures is given in Table 9. This is based on a melting temperature of pure HAN of 321 K = 48 °C and the coordinates of the eutectic point (73 mass-% HAN, 234 K = -39 °C) (Figure 6 and 7) [221].

Table 9: Solubility of HAN in water.

Temperature, °C	-20	0	10	20	30	40
Temperature, K	253	273	283	293	303	313
Solubility, mass-% HAN	81.5	85.3	91.6	94	97	98.5

Data source: [221]

The freezing and melting points of HAN solutions with 10 to 83.7 mass-% HAN were measured in gold DSC pans at temperatures down to 205 K (-68 °C) [222]. All HAN solutions exhibited weak supercooling effects, independent from the HAN concentration, that were much less pronounced than those of TEAN solutions evaluated as part of the same study. The peaks during heating were always much broader than the peaks during cooling. A eutectic point could not be found because the equipment did not cool below 205 K. A 93% HAN solution may contain both liquid and solid phases. Fig-

ure 8 shows a comparison of measured and calculated melting temperatures of HAN solutions in the range of 10 to 65% HAN. The solid line is the theoretical freezing point assuming the dissociation into two ions. Similar measurements were made for TEAN and LP-1845, as well as with added water. The melting temperatures of the HAN solutions at some specified concentration range were predicted rather well using the two-electrolyte assumption.

The following two HAN/H₂O melting-point diagrams (Figure 9 and 10) show a eutectic at about 230 K (−43 °C) and a HAN mol fraction of 0.28 [223]. These graphs are very similar to Figure 6 and 7.

The dependence of the glass transition temperature (T_g) of the binary system HAN-H₂O on the water content was investigated using DSC [224, 225]. It was found that T_g of the binary system exhibits the colligative property in the concentration range of 25–82 mol-% HAN, and when the HAN concentration is decreased as low as 25 mol-%, the property disappears, and the T_g rises surprisingly and is concentration independent. An attempt has been made to interpret this behavior in terms of the molecular clusters formed by various mol ratios of HAN/H₂O, which change with the content of H₂O in the system. It is considered that at most three molecules of H₂O can be incorporated with one HAN to form into the cluster, but when the content of H₂O increases as high as 75 mol-% (the mol ratio of HAN/H₂O is 1:3), only clusters of 2:3 mol ratio of HAN/H₂O are formed, and they are the most stable. See also [226].

3.3.1.2 Freezing Points and Melting Points of Ternary Systems

Ternary systems containing HAN, a solvent, and another oxidizer were developed as liquid oxidizers with the potential of becoming “green” replacements for other, more corrosive oxidizers such as N₂O₄ and red fuming nitric acid (RFNA). They were proposed as gas generants in oxygen generators (oxygen for welding or breathing air) and as oxidizers in bipropellants, hybrid propellants, and gelled solid propellants. In an effort to achieve low-freezing liquids, the melting-point diagrams of the ternary systems were graphed first, and they served to illustrate the choices that could be made in the selection process. Many of the compositions with the lowest freezing points chosen were close to eutectic points.

A family of low-melting eutectic salt mixtures was developed at Aerojet. Some of these oxidizer melts were later gelled with polyvinyl alcohol or similar water-soluble polymers, energized with metal powders, and cast into shapes like solid propellant grains. Others were mixed with water-soluble fuels to make liquid monopropellants. We are summarizing in this chapter here only the properties of eutectic nitrate melts (without added fuels or binders). The solution and emulsion propellant mixtures using these liquid oxidizers are discussed in *Encyclopedia of Monopropellants*.

A series of patents [227, 228] cover combinations of inorganic nitrates as oxidizers for rocket propellants, such as the following:

- ammonium nitrate, hydrazinium nitrate (HN), and hydroxylammonium nitrate
- ammonium nitrate and hydroxylammonium nitrate
- hydrazinium nitrate and hydroxylammonium nitrate
- ammonium nitrate, hydrazinium nitrate, and lithium nitrate

The melting points and safety properties of some of these low-melting oxidizers are summarized in Table 10.

Table 10: Melting points and hazard properties of eutectic oxidizer combinations.

*This is a known eutectic, included for reference only.

Data source: [227, 228]

Of the five mixtures tested, the three containing HAN resulted in the lowest melting combinations. One advantage of the eutectic formulations is that they have better thermal stability than HAN by itself, as shown by DTA and TGA measurements. The stability can be improved further by the addition of stabilizers: ammonium dihydrogen phosphate and 2,2'-dipyridyl, typically adding 1 mass-% each, based on the amount of HAN present. An oxidizer mixture containing these stabilizers called S-HAN5 (stabilized HAN with 5% AN) was widely used for formulating gelled solid propellants and monopropellants. It is interesting to note that the addition of as little as 1% of organic material may noticeably increase the drop-weight sensitivity.

The S-HAN patents by Bruenner are very similar to the OXSOL patents by Wagonman.

Figure 11: Melting-point diagram of the ternary HAN/AN/H₂O system. (Based on data from [229] and other sources.)

The melting-point diagrams of the ternary HAN/AN/H₂O and HAN/HN/H₂O systems were studied in the search for a low-melting liquid oxidizer that would be a non-toxic substitute for N₂O₄ or RFNA. The approximate contours of ternary melting-point diagrams of the HAN/AN/H₂O and HAN/HN/H₂O systems are shown in Figure 11 and 12, based on freezing-point data tabulated in [219].

There are insufficient data points to draw the isotherm lines with moderate accuracy. The lines drawn in Figure 11 and 12 require a lot of imagination and are shown only to illustrate the trend. The composition marked with an open triangle in Figure 11 is that of the preferred liquid oxidizer called OXSOL-1, containing 70% HAN, 15% AN, and 15% H₂O. Likewise, the composition marked with an open triangle in Figure 12 is that of the liquid oxidizer called OXSOL-2, containing 65% HAN, 22% HN, and 13% H₂O. A continuation-in-part of an earlier patent application by Wagaman was issued as U.S. patent 6299711 [230]. It is similar to the Mueller and Wagaman patent dated 1999, except it does not use HAN but also includes methylhydrazinium nitrate as a constituent. OXSOL-3 is a mixture containing AN, HN, and water (no HAN).

Figure 12: Melting-point diagram of the ternary HAN/HN/ H_2O system. (Based on data from [229], and other sources.)

Figure 13: Freezing-point diagram of the $\text{HAN}/\text{H}_2\text{O}_2/\text{H}_2\text{O}$ system. (Reproduced and modified from [230].)

Another patent covers solutions of HAN in hydrogen peroxide/water solvents [229, 230]. These oxidizers are called “PERHAN.” The freezing-point diagram of the HAN/H₂O₂/H₂O system is shown in Figure 13. The freezing point of a preferred PERHAN composition (62% HAN, 12.5% H₂O₂, 25.5% H₂O) is 233 K (−40 °C).

The freezing points and densities of binary HAN/H₂O and ternary HAN/HNO₃/H₂O mixtures were examined, and the activity coefficients of such solutions were compared to those of HN/HNO₃/H₂O mixtures [231]. Binary data (water activity as a function of the molal concentration) at 298 K (25 °C) for HAN and HN in nitric acid aqueous media were determined by direct water-activity measurements. Density deviations at 298 K (25 °C) were also observed. Ternary systems involving these nitrate salts and nitric acid were studied from the standpoint of simple solution theory. It was found that the HN/HNO₃/H₂O system did not exhibit simple behavior, which was due to hydrazinium(2+) dinitrate N₂H₆²⁺ formation. On the other hand, the system HAN/HNO₃/H₂O, which did not undergo major chemical interactions, satisfactorily followed the simple-solution rule as long as the water activity was higher than 0.84. No such abnormality was observed with HAN in HNO₃/H₂O solutions. For ternary simple solutions, it was possible to predict activity coefficients for each component.

Another series of monopropellant blends was made from hydrazinium nitrate, hydroxylamine, and water, and the code name was MHF-9, but these mixtures were not very stable [232] (*Encyclopedia of Monopropellants*).

3.3.2 Density of HAN

The density of solid HAN is 1.841 g/cm³ (from X-ray data). It is thus denser than ammonium nitrate or hydrazinium nitrate. Other sources give the density at 298 K as 1.830 g/cm³ [233].

3.3.2.1 Density of Binary HAN Solutions

The knowledge base for the density of HAN solutions in water as a function of concentration has evolved, and data have been refined over the course of several decades. Density has often been used as a quick indication of HAN assay during preparation and concentration of HAN solutions. The accuracy of this method suffers from contamination by nitric acid and ammonium nitrate.

The first approximation, derived from 1 to 13-M HAN solutions at room temperature, was

$$\rho = 1.0000 + 0.0369M$$

where ρ is the density in g/cm³ and M is the molarity (Sasse, 1976, unpublished data). Extrapolating to 100% HAN would point to a density of 1.81 g/cm³, a number that was

used by many investigators in the 1970s. Later data from Thiokol [206] indicated that the density is not a true linear function of the molarity. An equation for the mid-range from 2.1 to 17.3-M HAN was fitted to the data, but extrapolation to either end was discouraged:

$$M = 26.04\rho - 26.38$$

$$\rho = 1.013 + 0.0384M$$

The main interest was in solutions near the target concentration of 13 M. Thus, a more accurate set of data was created [206] for the range from 11.7 to 14.3 M and is represented by

$$\rho = 1.12292 + 0.03099M$$

where ρ is the density in g/cm^3 and M is the molarity (as quoted by Decker et al. [220]). This curve fit was made to give an optimum match over a medium range, but it was not forced to go through the known points at 0 and 99.9% HAN.

The density of HAN solutions as a function of HAN concentration is shown in Figure 14 [234]. A single data point for LP1846 = XM46, marked with an $\times$, is shown for comparison.

Figure 14: Density of HAN solutions as function of molarity. (Reproduced and modified from [234].)

Figure 15 gives a comparison of four sets of density data for HAN solutions developed during the period 1976 through 1989. A similar comparison of HAN solution-density data from three different sources was compiled and curve-fitted [235]; see Figure 16.

Figure 15: Comparison of data for density of HAN solutions in water at room temperature (Image created by Schmidt 2020.)

Data source: [236, 237]

Other data points for densities of HAN solutions are listed in Tables 11 and 12.

If the density of HAN solutions is plotted against the mass fraction, the curve is slightly concave. This is typical for electrolytes where the ions are surrounded by a sheath of water molecules in a tightly held structure. Figure 17 shows the density of aqueous HAN solutions at 298 K in comparison to densities of two other oxidizers [238]. The AN data were measured at higher than room temperature (323 K) because AN is less soluble in water than the other two oxidizers.

The partial molar volumes of HAN and other oxidizers were measured so that the theoretical density of oxidizer/fuel/water mixtures in monopropellants could be calculated assuming additive behavior of the partial molar volumes in mixtures. As

Figure 17: Density of aqueous HAN solutions in comparison to other oxidizers. (Reproduced and modified from Kappenstein, Batonneau, Perianu and Wingborg [238] with permission from Dr. Charles Kappenstein.)

a start, the reciprocal density (i.e., the specific volume) was plotted vs. the mol fraction of oxidizer, as shown in Figure 18.

The curves in Figure 18 are straight lines, such that their shape can be expressed by a simple linear function

$$V_m = V_{m\text{H}_2\text{O}} \times X_{\text{H}_2\text{O}} + V_{m\text{HAN}} \times X_{\text{HAN}}$$

$$V_m = V_{m\text{H}_2\text{O}} + (V_{m\text{HAN}} - V_{m\text{H}_2\text{O}}) \times X_{\text{HAN}}$$

The partial molar volumes of the salts are derived from the intercept of the lines. The results are summarized in Table 13.

Table 13: Extrapolated partial molar volume and density of pure ionic liquid oxidizers.

Compound name	Formula	Molar volume, cm ³ /mol	Density of pure ionic liquid (no solvent), g/cm ³
Ammonium nitrate	NH ₄ NO ₃	52.00(15) ^a	1.539(5) ^a
Ammonium dinitramide	NH ₄ N(NO ₂) ₂	74.06(13)	1.675(3)
Hydroxylammonium nitrate	NH ₃ OH NO ₃	55.45(19)	1.732(6)

^aNumbers in parentheses designate the standard deviation of the last digits.

Data source: [238]

Figure 18: Molar volume of aqueous HAN solutions vs. mol fraction HAN, in comparison to other oxidizers. (Reproduced and modified from Kappenstein, Batonneau, Perianu and Wingborg [238] with permission from Dr. Charles Kappenstein.)

The apparent molar volume of a solution is obtained by assuming that it is made up of two additive contributions, one from the water solvent and the other from the solute. The partial molar volume of the solute can be calculated by subtracting the volume of water from the density of the solution and subtracting the density of the solute:

$$V_s = \frac{1000\left(\frac{1}{D} - \frac{1}{D_i}\right)}{G + \frac{E}{D}}$$

where

V_s = apparent molar volume of solute, cm³/mol

D = density of solution, g/cm³

D_i = density of solvent, g/cm³

G = molality of solution, mol/1000g

E = molecular mass of solute, g/mol

The conversion of molarity to molality is done by

$$G = \frac{1000M}{(1000D - ME)}$$

where M is the molarity of the solution. The mol fraction X of the solute is obtained from

$$X = \frac{G}{\left(G + \frac{1000}{B}\right)}$$

where B is the molecular mass of the solvent (H_2O ; $B = 18.0153$). Instead of plotting the partial molar volumes against the reciprocal density, a better correlation can be obtained by plotting the partial molar volumes against a concentration parameter χ

$$\chi = \frac{\sqrt{X}}{1 + \sqrt{X}}$$

where X is the mol fraction HAN. This correlation was used at Olin Chemicals for calculating the densities not only of the HAN solution products but also of feedstock and mixed electrolytes at various stages of the HAN production process [239]. The slope of the linear function (X coefficient) shown in Figure 19 is 19.2226. The intercept at infinite dilution is at $47.1141 \text{ cm}^3/\text{mol}$. The density at the pure HAN end (1.68 g/cm^3) is closer to that of molten HAN than crystalline HAN. The same method was also used for AN and TEAN solutions. The method is useful for obtaining densities of solutions at constant temperature over a wide range of concentrations if only the density of the solid salt and one density point of the solution are available.

Figure 19: Apparent molar volumes of HAN at 20 °C as a function of concentration parameter χ . (Reproduced and modified from [162].)

Density measurements at the U.S. Army's Ballistic Research Laboratory (BRL) by Sasse et al. [236, 240] were made not only on HAN in water but also on its deuterium analog in heavy water; see Table 14.

^aAnhydrous melt

^bCrystalline solid, from X-ray data, [241]

Data source: [236], except data points marked with^b

The data in Table 14 have been curve-fitted to a second-order polynomial instead of a linear progression formula.

For HAN in H₂O:

$$\rho = 0.9935 + 0.04630M - 0.0004007M^2$$

For HAN-D4 in D₂O:

$$\rho = 1.1045 + 0.04646M - 0.0005581M^2$$

Figure 20 shows the data from Table 14 and a second-order polynomial curve fit for the mid-range. The standard deviation for density using the quadratic equation is three times smaller than for data approximated by the linear equation.

Figure 20: Comparison of solution densities for HAN/H₂O and HAN-D₄/D₂O. (Image created by Schmidt 2020 based on data from [236].)

3.3.2.2 Density of Ternary HAN Solutions

In addition to binary HAN/water solutions, ternary mixtures of HAN/AN/H₂O, HAN/HN/H₂O, and HAN/H₂O₂/H₂O have been formulated as liquid oxidizers. The measured density of OXSOL-1 at 296.2K (23.1°C) is 1.539g/mL. The patent [242] contains tabulated density data for a wide range of HAN/AN/H₂O mixtures in

Figure 21: Density of HAN/H₂O₂/H₂O solutions. (Reproduced and modified from [229, 230].)

addition to that of OXSOL-1. The measured density of OXSOL-2 at 296.2 K (23.1 °C) is 1.552 g/mL.

Densities of ternary HAN/H₂O₂/H₂O solutions are graphed in Figure 21. The density of PERHAN (62% HAN, 12.5% H₂O₂, and 25.5% H₂O, marked with a triangle Δ) is 1.439 g/mL at 298 K.

3.3.3 Viscosity of HAN Solutions

The viscosity of HAN solutions increases abruptly as the temperature of the solutions drops to close to the glass transition temperature T_g . Viscosity measurements as a function of water content and temperature were conducted to validate theoretical models in an attempt to represent the molecular structure of ion clusters in solution.

The viscosities of HAN solutions as a function of concentration based on data from van der Hoff, Bunte, and Donmoyer 1986 [243] are summarized in Table 15. Additional density and viscosity data are in Table 16. Table 17 gives viscosity of HAN solutions with different concentrations at various temperatures.

Table 15: Viscosity of HAN solutions as a function of concentration.

Concentration	Viscosity at 293 K (20 °C)	
M	mPa s	cPs
0 (pure water)	1.002	1.002
0.1	1.02	1.02
0.5	1.06	1.06

Figure 22: Dynamic viscosity of HAN and HN solutions at 273 K. (Reproduced and modified from [235].)

The curves obtained when plotting the dynamic viscosity of HAN solutions vs. the mass fraction in comparison to that of HN solutions show that solutions of the two salts in water behave very similarly (Figure 22) [235]. The viscosity increases steeply as the concentration approaches saturation.

The kinematic viscosity of 13-M HAN as a function of temperature is shown in Figure 23.

Figure 23: Kinematic viscosity of 13-M HAN as a function of temperature. (Reproduced and modified from [235].)

3.3.4 Vapor Pressure and Boiling Point of HAN Solutions

The vapor phase above HAN solutions consist essentially only of water. HAN itself is not volatile as long as there is some water in the solution.

Because of a lack of thermal stability, one will generally avoid heating HAN solutions to the boiling point for any length of time. However, because most HAN is produced in dilute solutions and has to be concentrated for use as a propellant, the boiling behavior of HAN solutions has been studied in detail [246]. Two sets of experiments were conducted, one in an open system (allowing water to escape) and the other in an open system with a reflux condenser that returned all water vapor to the sample. Both were done under inert gas because the presence of oxygen may cause acceleration of “fizz” reactions. The potentially **hazardous** tests were conducted with

10-mL samples in 30-mL glass flasks and extended for up to 3 h. A sample of 12.48-M HAN was refluxed and analyzed before and after the experiment. The boiling point was 405 K (132°C) at the beginning and 402 K (129°C) at the end of the 2.5-h experiment. The analysis showed a 6% loss in HAN and a gain of water. The gases escaping were nitrogen and nitrous oxide in a mol ratio of 1:2. The boiling points for different HAN concentrations are given in Table 18.

Table 18: Boiling points of HAN solutions.

Composition, molarity		Boiling point	
HAN	Water	K	°C
0	55.56	373.15	100
4.0	43.72	380.15	107
9.0	28.99	388.15	115
12.0	20.16	400.15	127
12.48	16.72	405.15	132
13.0	17.21	402.15	129
13.0	17.21	407.15	134
15.8	8.97	418.15	145

Data source: [236]

Pure HAN does not have a measurable vapor pressure. Hydroxylammonium nitrate solutions are ionic liquids, and as such have been proposed as working fluids for electric colloid thrusters, which operate only in vacuum. In such electrospray thrusters, the HAN solution would have to be introduced as an aerosol, which can then be ionized to create a plasma and then be accelerated in an electric field, similar to an ion engine [247]. A modeling effort was started to better understand the ionization processes of vaporized ionic liquid mixtures. Differences were noticed between decomposition reactions at elevated pressures and those occurring when HAN was vaporized and ionized in vacuum. The species in the vacuum decomposition spray were analyzed with a residual gas analyzer and showed a large percentage of nitric oxide. A mixture of 1-ethyl-3-methylimidazolium ethyl sulfate ([Emim][EtSO₄]) and HAN is an energetic monopropellant potentially suitable in a multi-mode chemical-electric microtube-electrospray micropropulsion system [248].

3.3.5 Compressibility of HAN Solutions

Liquid-propellant guns operate at much higher pressures than rocket engines. For this reason, the compressibility of HAN, HAN solutions, and HAN-based propellants has been investigated. Although this is not needed for normal rocket propellant opera-

tions, certainly not without prior addition of a fuel, the data are listed here nevertheless, just in case they are needed.

3.3.5.1 Velocity of Sound in HAN Solutions

The velocity of sound is easier to measure than the compressibility of fluids, and the two properties can be converted by simple equations. There are substantially more data on velocity of sound and compressibility measurements of formulated, mixed HAN-based propellants than on the ingredients by themselves.

A cell for high-pressure sound velocity measurements of liquids in a Birch-Bridgman pressure vessel was used to determine the velocity of sound in 2, 4, 9, and 13-M HAN and in several TEAN solutions at room temperature at pressures up to 4000 bar (55 ksi) [249–251]. The velocity of sound as a function of pressure and concentration is shown in Figure 24.

Figure 24: Velocity of sound of HAN solutions as a function of pressure and concentration. (Reproduced and modified from [251].)

The velocity of sound and the attenuation of sound in HAN solutions was measured at 203 to 294 K using ultrasound and Rayleigh-Brillouin scattering methods in the frequency ranges of 10 MHz and 8–14 GHz [252, 253]. The data were curve-fitted to obtain the dependence of the velocity of sound on the sample temperature. Similar measurements were performed on TEAN solutions.

3.3.6 Gas Solubility in HAN Solutions

During the evaluation of HAN-based monopropellants as liquid gun propellants, inadvertent ignition due to adiabatic compression of gas bubbles was an ongoing concern. The release of gas bubbles is most likely a worst-case scenario if the propellant is saturated with gas. Therefore, the solubility of gases in HAN and HAN-based monopropellants has been investigated (*Encyclopedia of Monopropellants*).

3.3.7 Thermodynamic Properties of Hydroxylammonium Nitrate

3.3.7.1 Heat Capacity of HAN Solutions and Solid HAN

Abrupt changes in the heat capacity of HAN solutions occur when the temperature is lowered close to the glass transition temperature. Heat capacity measurements were used as a sensitive indication of changes taking place in the molecular structure of the associations of ions and solvates in clusters. The interpretation of these measurements is given in Section 3.3.8.2 (molecular structure).

It has been attempted to derive the heat capacity and other thermodynamic functions of solid and molten HAN from the spectroscopic and XRD data using statistical thermodynamics and a Monte Carlo method. A formula not previously found in the literature was derived for the heat capacity at constant pressure for a system at given density and temperature from a single Monte Carlo run [254]. X-ray and neutron diffraction measurements have been made of HAN and/or deuterated HAN. The crystalline structure has been determined for a wide range of temperatures. The X-ray and neutron diffraction data have been jointly analyzed to display the details of the valence electron distribution in HAN. X-ray and neutron liquid scattering experiments have yielded the total structure factor of molten HAN. Theoretical models of the partial structure factors (and from them, the total structure) of molten HAN have been made using the Percus-Yevick hard-sphere model. As a beginning approach to a perturbation theory of the system, a system of rigid ellipses was studied [255].

Other heat-capacity data points for three different HAN concentrations at one temperature are listed in Table 19. Heat-capacity data for two different HAN concentrations at five different temperatures are listed in Table 20.

Table 19: Heat capacity of HAN solutions.

HAN concentration, molarity	Heat capacity at 293 K, J kg ⁻¹ K ⁻¹
13	1570
10.7	1553
9	1733

Table 20: Heat capacity C_p of HAN solutions.

Temperature, K	Temperature, °C	3.2-M HAN		13-M HAN	
		J g ⁻¹ K ⁻¹	cal g ⁻¹ °C ⁻¹	J g ⁻¹ K ⁻¹	cal g ⁻¹ °C ⁻¹

3.3.7.2 Enthalpy of Fusion of HAN

The enthalpy of fusion of HAN was determined from solubility and phase diagram results to be $11 \pm 2 \text{ kJ} \cdot \text{mol}^{-1}$ [210].

Direct measurement of the enthalpy of fusion was done in a calibrated differential scanning calorimeter [215]. The onset of melting of α -HAN was at $35.72 \pm 0.65^\circ\text{C}$, and the average heat of fusion was $26.97 \pm 2.05 \text{ cal/g} = 112.8 \pm 8.6 \text{ J/g}$. The onset of melting of β -HAN was at $47.73 \pm 1.69^\circ\text{C}$, and the average heat of fusion was $26.72 \pm 1.81 \text{ cal/g} = 111.8 \pm 7.6 \text{ J/g}$. There was no significant difference between the latent heats of fusion of the two crystal modifications.

3.3.7.3 Enthalpy of Formation of HAN

The enthalpy of formation of solid HAN is mostly of academic interest since HAN is almost never used in the solid state as a rocket propellant. We really need the enthalpies of formation of various HAN solutions and of HAN in solution together with other ionic species serving as fuels in monopropellants.

3.3.7.4 Enthalpy of Formation of Solid Hydroxylammonium Nitrate

The most frequently quoted number for the standard enthalpy of formation of solid HAN is $366.5 \text{ kJ/mol} = 87.6 \text{ kcal/mol}$ [256, 257]. The source of this number is most likely [216].

PEPCODED.DAT has an enthalpy of formation of HAN of $-843.0 \text{ cal/g} = -80.96 \text{ kcal/mol} = -338 \text{ kJ/mol}$ [258]. The source of this number is not known.

Kounalakis and Faeth [259] estimated the enthalpy of formation of HAN and TEAN from the Doraiswamy group contribution method and predicted 399 kJ/mol (95.3 kcal/mol) for HAN and -776 kJ/mol (-185.5 kcal/mol) for TEAN.

Kuwahara calculated the theoretical performance of AP/HTPB/Al, AN/HTPB/Al, and HAN/HTPB/Al solid propellants and used an enthalpy of formation of -4358 kJ/kg [217]. That translates into -418.4 kJ/mol .

Other sources (Ashcraft, Raman, and Green [260]; Meng et al. [261]) quote the enthalpy of formation as $-333.4 \text{ kJ/mol} = -79.68 \text{ kcal/mol}$, but that may be for dissolved

HAN in aqueous solutions at infinite dilution. The enthalpy of dissolution of HAN in water was reported as 22.5 kJ/mol, which partially accounts for the difference in these numbers.

3.3.7.5 Enthalpy of Formation of Hydroxylammonium Nitrate Solutions

The difference between the enthalpy of formation of solid HAN and the enthalpy of formation of HAN solutions is the enthalpy of dissolution. Table 21 gives the enthalpy of dissolution of HAN compared to that of other high-energy oxidizers [262]. All of these salts cool off when dissolved in water, a phenomenon that is used with advantage with ammonium nitrate (AN) in two-component instant ice packs for first aid in sports injuries.

Table 21: Standard enthalpy of dissolution of HAN compared to that of other oxidizers.

Compound	Standard enthalpy of formation, kJ/mol		Enthalpy of dissolution, kJ/mol
	Solid	In solution at infinite dilution	
NH_3OHNO_3	-366.5	-344.8	+22.5
NH_4NO_3	-365.4	-339.9	+25.3
$\text{N}_2\text{H}_5\text{NO}_3$	-246.9	-215.1	+31.8

Data source: [262]

3.3.7.6 Enthalpy of Formation of Hydroxylammonium Nitrate Vapor

Various computational chemistry methods have been used to predict the enthalpy of formation of HAN vapor from its molecular structure. Although HAN vapor would exist only during the sublimation of HAN at very low pressures, this condition can be simulated successfully with modern computational methods. We cite one of these methods here as an example of how the potential hazards of energetic materials can be predicted without getting one's fingers wet (or burned) in the laboratory. The calculated gas-phase heats of formation at 298 K were -271 and -242 kJ/mol (-64.8 and -57.8 kcal/mol) using AM1 and PM3 methods, respectively [263]. In order to validate the results, the high-level quantum mechanical method G2MP2 from the Gaussian 03 suite of programs was also used to calculate the heat of formation of HAN. The suggested heat of formation of -255 kJ/mol (-61 kcal/mol) is about the average of the results using the AM1 and PM3 methods. One must know the heat of sublimation to convert these numbers to the enthalpy of formation of solid HAN.

3.3.8 Molecular Structure of Hydroxylammonium Nitrate

3.3.8.1 Molecular Structure of Solid Hydroxylammonium Nitrate

The molecular structure of the ion pair used for modeling is illustrated in Figure 25.

Figure 25: Molecular structure of a HAN ion pair in the gas phase. (Patterned after [263].)

The crystal and molecular structures of pure HAN and HAN-D4 were obtained by single-crystal X-ray diffraction (XRD) [264]. Hydroxylammonium nitrate crystallizes in monoclinic crystals $P2_1/c$ with the lattice parameters of $a = 4.816 \text{ \AA}$, $b = 6.800 \text{ \AA}$, $c = 10.728 \text{ \AA}$, and $\beta = 99.35^\circ$ [265, 241]. HAN and its perdeuterated homolog HAN-D4 are isostructural and have very similar crystal parameters, bond distances, and bond angles. The local environment of the NH_3OH^+ ion is shown in Figure 26 in an illustration copied from [266].

All of the hydrogen (or deuterium) atoms are involved in hydrogen bonding to neighboring oxygen atoms, with H(2) being bifurcated between O(2) and O(3). The hydrogen-bond contacts are shown as dashed lines. The strongest hydrogen bonding is between the hydrogen on the $-\text{OH}$ group and one of the oxygens on a neighboring nitrate ion.

The theoretical electron-density analysis of five crystals including HAN was calculated using molecular orbital computational chemistry methods [267]. The theoretical results were compared to the experimental results available from XRD. The theoretical calculations give electron-density distributions in good agreement with the experimental results for some compounds, but obvious differences between the calculated electron-density distributions and experimental density distributions for HAN were noted. Some improvement in agreement between experimental and calculation results can be achieved when the basis sets are changed from STO-3G to 3-21G.

Figure 26: The microenvironment of $\text{ND}_3\text{OD}^+\text{NO}_3^-$ ions in crystalline HAN. (Reprinted from [266], with permission from © 1986 American Chemical Society; permission conveyed through RightsLink.)

X-ray and neutron diffraction measurements have been made of HAN and/or deuterated HAN [254, 255, 268]. The crystalline structure was determined for a wide range of temperatures, looking for phase changes similar to those occurring in AN. The X-ray and neutron diffraction data were jointly analyzed to display the details of the valence electron distribution in HAN crystals.

Electron-density distributions in four compounds were analyzed by simultaneous modeling of X-ray and neutron diffraction data [269]. The model compounds, HAN, and three other molecules represented a wide range of atom–atom interactions and provided a stringent test for a single electron-density model. It was found that the X-ray and neutron models converge to a single model when appropriate considerations have been included and that the X + N technique is helpful in reaching a higher level of confidence. Model considerations that were explored included anharmonic thermal motion (third-order and fourth-order), secondary extinction correction, proper weighting of the two data sets, and application of charge constraints.

3.3.8.2 Molecular Structure (Clusters) in Hydroxylammonium Nitrate Solutions

Hydroxylammonium nitrate solutions contain hydroxylammonium ions, nitrate ions, water, undissociated HAN, and very small amounts of hydroxylamine free base and

free nitric acid. The ions are highly associated, connected by hydrogen bonds and water molecules forming bridges. The ions associate in clusters. Ion pairing can be observed in solutions with concentrations as low as 2-M HAN. Cluster formation is responsible for many of the unique properties of HAN solutions, e.g., their high viscosity and the rate of proton exchange.

The intermolecular distances of hydrogen-bonded oxygen atoms in HAN solutions can be derived from the sharpness of IR peaks [270]. At 308 K (35 °C) and 9.5-M HAN, the O—H band of water is very broad, corresponding to a wide variation of O...O distances. The distribution narrows with increasing concentration and shifts to lower frequencies (shorter O...O distances) with decreasing temperature. At 213 K (−60 °C) there is an abrupt shift due to the formation of a glassy state. The intermolecular distance of O...O in $\text{H}_3\text{NOH}\cdots\text{O}$ is very sharp at 2.63 Å, and the distance in $\text{HO}-\text{H}\cdots\text{O}$ varies widely depending on temperature and concentration, centered around 2.9 Å. A large H-bond shift and its narrow distribution suggest a highly ordered ion-pair configuration in the liquid.

HAN is fully dissociated into the hydroxylammonium and nitrate ions in dilute aqueous solutions. As the salt concentration increases past 2 mol/L, beginning ion pairing is observed, the ion pair being formed between the hydrogens of NH_3OH^+ and the oxygens of NO_3^- . Computational chemistry molecular modeling studies can describe the structure of these ion pairs and the clusters that form as HAN concentration is increased and can explain the fate of the water solvent tucked away and immobilized between the ions. The properties of concentrated HAN–water mixtures are quite different from those of aqueous solutions and are readily explained with the assistance of these molecular modeling studies.

Ion clusters can be studied in solution or in the gas phase. Compounds that are not stable enough in the gas phase for experimental study of cluster formation can be modeled by computational chemistry to obtain images of their spatial arrangements minimizing the free energy.

The glass transition temperatures of HAN/ H_2O solutions were determined by DSC [271]. It was found that T_g behaves as a colligative property and remains nearly constant at 372.85 K (−99.7 °C) in the concentration range of 25–82 mol-% HAN. When the HAN concentration is lowered to below 25 mol-% HAN, T_g rises surprisingly, and for a wide range it is independent of the HAN concentration. Researchers have attempted to explain this behavior by the formation of clusters [272, 273]. It was assumed that three molecules of water at most can be incorporated in a cluster with HAN. The most stable clusters are those containing three molecules of water for every two molecules of HAN, which form when the HAN concentration is below 25 mol-%.

Structures and energies of gas-phase HAN clusters can be determined using density functional theory (DFT). Three stable cluster configurations were found for HAN that involve strong hydrogen bonding between hydroxylamine and nitric acid molecules and their ions [274]. In the most stable configuration, both the oxygen and the nitrogen of hydroxylamine were found to be hydrogen bonded to sites on

the nitric acid molecule. In the less stable HAN structures, only the oxygen or the nitrogen of hydroxylamine are hydrogen bonded. There are two stable structures for the $(\text{HAN})_2$ complex. The more stable structure is ionic, with the nitric acid proton having transferred to the nitrogen of hydroxylamine. Strong electrostatic and hydrogen-bonding interactions stabilize this structure. The other stable form of $(\text{HAN})_2$ has fewer hydrogen bonds and is composed of interacting neutral nitric acid and hydroxylamine molecules. Proton exchanges are very fast for the HAN configurations. The saddle points for the proton exchange process are ionic forms of HAN with interacting HONH_3^+ and NO_3^- moieties. These ionic structures are 13.5 and 13.6 kcal/mol higher in energy than the neutral hydrogen-bonded complexes of HONH_2 and HNO_3 from which they are formed. The electrostatic attractions between the ions are sufficient to stabilize the ionic form of $(\text{HAN})_2$, whereas in the HAN “monomer” the interaction energy for single HONH_3^+ and NO_3^- ions is not sufficient to compensate for the energy required for proton transfer from nitric acid to the hydroxylamine group. Alkylation of the NH_2 group changes the proton transfer barriers; see Section 6 on alkylhydroxylamines.

The images used for illustrating the appearance of HAN clusters here are only two-dimensional on paper. In reality, this is a three-dimensional (3-D) network. It would require some 3-D software to illustrate clusters on a computer screen and enable the viewer to rotate the molecule and view it from different angles.

HAN clusters become even more complex after the addition of water-soluble fuels in an effort to create monopropellants. Many of these fuels are ionized salts or are molecules that actively participate in the formation of hydrogen bonds.

Theoretical models have been developed to explain the unusual behavior of the viscosity of HAN solutions (and ternary mixtures containing HAN, water, and a fuel) as the temperature of the liquid approaches the glass transition point. Anharmonic effects in ammonium nitrate and HAN clusters due to hydrogen bonding are responsible for the unique properties of their aqueous solutions [275]. The covalent and ionic clusters of ammonium nitrate and hydroxyl ammonium nitrate were characterized using DFT and second-order vibrational perturbation theory. The most stable structures are covalent acid–base pairs for the monomers and ionic acid–base pairs for the dimers. The hydrogen-bonding distances are greater in the ionic dimers than in the covalent monomers, and the stretching frequencies are significantly different in the covalent and ionic clusters. Calculations of geometries, frequencies, and shielding constants have provided insight into the significance of anharmonic effects in ionic materials, as well as data that will be useful for the illustration of molecular mechanical force fields in ionic liquids. Anharmonic effects are particularly important for the study of proton transfer reactions in ionic materials, such as those that initiate the decomposition of HAN.

3.3.9 Optical Properties of Hydroxylammonium Nitrate

3.3.9.1 Spectra of Hydroxylammonium Nitrate Solutions and Solid Hydroxylammonium Nitrate

Absorption spectra of HAN solutions in the UV and IR regions have been taken for several reasons: They are useful in studying the unique properties of ionic, highly associated (clustered) liquids, and they are used as analytical methods to verify the nominal composition of propellant mixtures containing HAN and to detect unwanted contaminants. Another reason that the spectra of HAN and HAN-based propellants over the entire range of the electromagnetic spectrum needs to be known is the proposed use of laser or microwave heating as a method for igniting these hard-to-ignite propellants. The amount of energy absorbed depends on choosing the correct frequency for the source of radiation, matching the laser output with the absorption spectrum of the compound to be ignited. Spectra discussed here cover a wide range of the electromagnetic wave spectrum. A separate section also includes induced methods such as nuclear magnetic resonance (NMR) and electron spin resonance spectroscopy.

UV Spectra of Hydroxylammonium Nitrate Solutions

The UV and IR spectra of HAN solutions and propellants are of interest for laser-ignition studies. Because HAN-based propellants are ultimately safe, and some will not ignite even if hit with the flame of a welding torch, various alternate ignition methods have been studied for ignition in liquid guns or rocket engines. This includes laser ignition.

IR Spectra of Hydroxylammonium Nitrate Solutions

Infrared spectra of HAN solutions are valuable diagnostic tools to monitor HAN concentrations during its synthesis, to verify the absence of contaminants, and to identify and analyze decomposition products formed during extended storage or intermediates formed during rapid heating to the point of ignition. Infrared spectroscopy is an ideal method for analysis of HAN and HAN contaminants in the solid state or in aqueous solutions [276]. The mid-IR spectrum of HAN solutions contains several distinct, non-overlapping peaks that are characteristic for its ingredients. The line broadening of the peaks indicates strong hydrogen bonding of several of the species in aqueous solution. Infrared spectra of HAN solutions at atmospheric pressure were obtained by placing a capillary film between AgCl windows. Changes in the IR spectra of all three components, NH_3OH^+ , NO_3^- , and H_2O , provided a consistent picture of the interactions between these species. The nitrate spectrum was most sensitive to inter-species interactions because distinctive bands due to ion pairing and hydration were observed.

The bands below 2000 cm^{-1} are due to intramolecular vibrations of water, NH_3OH^+ , and NO_3^- ions. Spectra at high pressures were obtained using a variable temperature diamond anvil cell. From these spectra, qualitative and quantitative

information about hydrogen bond lengths and the interspecies distance distributions in aqueous HAN solutions was obtained as a function of concentration (7 to 17 M), temperature (153 to 333 K = -120 to +60 °C), and pressure (0.1 to 7100 MPa). Absorption bands were identified using isotopic uncoupling techniques (deuterium analogs) for the O—H...O and N—H...O hydrogen bonds in conjunction with frequency–distance correlations [277]. Replacing hydrogen with deuterium shifts the absorption bands that are due to N—H bonds and O—H bonds, as seen in Figure 27, which shows IR spectra of normal and deuterated HAN (dHAN).

Infrared spectra of aqueous solutions of dHAN (11M ND₃ODNO₃ (= dHAN) in D₂O) were recorded at pressures ranging from 0.101 kPa to 1.767 GPa [278]. Comparing absorption bands of isotope-substituted dHAN to those of normal HAN allows

Figure 27: Transmittance IR spectra for 13-M HAN and deuterated HAN. (Republished and modified from [270] with permission of © 1988 Springer Nature BV; permission conveyed through Copyright Clearance Center Inc.)

one to measure hydrogen (deuterium) bond distances between OD (OH) groups and neighboring O atoms. Compressing the solution in a diamond anvil cell to extremely high pressures shifted the IR absorption bands in response to the changing interatomic distances. As a result of the pressurization, the N—O stretch shifted from 991.7 to 1012.2 cm^{-1} , and the NO_3^- bending mode shifted from 825.7 to 816 cm^{-1} .

The broad absorption band at 2730 cm^{-1} resulting from the $-\text{NH}_3^+$ bending combination mode of HONH_3^+ has been used in kinetic studies of aqueous HAN thermal decomposition [279].

The IR spectrum of an 85% HAN solution shown in Figure 28 is very useful because the exact wave numbers were written next to the peaks [280].

Figure 28: IR spectrum of 85% HAN solution. (Reprinted and modified from [281].)

The vibration bands at 3166, 3076, 2998, 2981, 1761, 1520, 1195, and 1009 cm^{-1} were assigned to the NH_3OH^+ group by analogy with NH_3OHCl . The intense band at 2737 cm^{-1} is a combination of the rotation band and the symmetrical deformation band of NH_3OH^+ (1195 and 1520 cm^{-1} , respectively). The stretching vibrations of the O—H bond are identified at 3552, 3358, 1609, and 684 cm^{-1} . The influence of the hydrogen bonding manifests itself in the position of the stretching vibration band and the deformation band of the O—H groups. The N—O bond has a doubly degenerate band at 1387–1342 cm^{-1} and a deformation band at 824 cm^{-1} . The concentration of the HAN solution seems to influence the vibrational bands position in the IR range.

Thus, an increasing water concentration shifts the characteristic bands of N—H to higher wave numbers. For the stretching vibrations of the N—O bond, the dilution effects a slight increase in band wave numbers located at 1387–1342 and 684 cm^{-1} . The stretching vibrations of O—H bonds (3552 and 3358 cm^{-1}) undergo an expansion that increases with dilution.

IR Spectra of Solid Hydroxylammonium Nitrate

Solid and water-free HAN is relatively difficult to obtain, and it is difficult to prevent it from absorbing water from the atmosphere while the sample is being prepared and mounted in the spectrometer.

Infrared studies of HAN and HAN-D4 spectra conducted in the 1980s often fail to give proper credit to an earlier study of deuterated hydroxylammonium salts, including the nitrate and perchlorate (Rocchicciolo [282]). The IR band assignments for HAN from this precedent source are summarized in Table 22. All bands, with the exception of the νNO band and those of the anions, are affected by deuteration. A similar table for HAP is presented in a later section of this book.

Table 22: IR absorption-band assignments for HAN and d-HAN spectra.

Wavenumber		Assignment
Hydrogen	Deuterium	
3045(f)	2380	νOH
2995(F)	2240	νNH_3^+ anti-symmetric
2900(F)	—	νNH_3^+ symmetric
2665(m), 2380, 1895(f)	2020	Combinations
1580(F), 1559(f)	1142	δNH_3^+ degenerate
1505, 1480, 1470(m)	1120	δNH_3^+ symmetric
1193(F)	903	Rotational NH_3^+
1165(F)	870	δOH
998(F)	990	νNO
529(m)	—	Torsional OH
1365(F), 830(m), 724(f)	—	NO_3^-

Data source: [282]. Absorption band strength legend: (F) very strong, (f) strong, (m) medium.

Deuterating any hydrogen-containing compound and observing the isotope shift in IR absorption lines is a useful tool in assigning IR bands. HAN and HAN-D4 are isostructural and possess similar bond distances and angles. There is no water of crystallization in the crystal lattice. The IR spectrum of HAN and its fully deuterated analog HAN-D4 was measured between 170 and 470 K [266]. Twenty-four bands between 800 and 3140 cm^{-1} were resolved, and about half of them were tentatively assigned to fundamental vibrations. In addition to the fundamentals, a number of overtone/com-

bination bands appear that have become enhanced by N—H and O—H vibrational anharmonicity caused by hydrogen bonding. Figure 29 presents the mid-IR spectrum of partially dry solid and melted HAN. A shoulder at 3140 cm^{-1} depends on the amount of water in the sample.

Figure 29: Mid-IR spectrum of partially dry solid (A) and melted (B) HAN. (Reprinted and modified from [266], with permission from © 1986 American Chemical Society; permission conveyed through RightsLink.)

There has been some uncertainty about the assignment of absorptions in the $2620\text{--}2750\text{ cm}^{-1}$ range of aqueous HAN. At one time it was proposed that these may be due to $\nu(\text{OH})$ of a very short $\text{NH}_3\text{OH}^+\cdots\text{ONO}_2^-$ contact ion pair, but Cronin and Brill now assign this to $-\text{NH}_3^+$ combination bands rather than to an OH fundamental. Solid HAN that was relatively water-free was cooled to 170 K while its IR spectrum was recorded. There were normal frequency shifts but no visible solid–solid phase transitions. Solid HAN was then heated through its melting point. All of the bands broadened upon melting.

IR spectra of HAN and its decomposition products were used to study the rapid-heating-rate thermal decomposition of HAN and LP1845 using the FTIR/temperature profiling technique [283]. This is part of an eight-part investigation final report in which the investigators also examined model nitrate solutions and compared their spectra to those of HAN. Acoustic levitation was developed as an IR spectroscopy sample-holding technique to develop non-intrusive droplet studies by IR spectroscopy.

Figure 30 shows the IR spectrum of solid HAN obtained by Kuwahara and colleagues [217].

Raman Spectra of Hydroxylammonium Nitrate Solutions

Raman spectra of HAN solutions and HAN-based monopropellants have been measured mostly for academic interest. There have not yet been any analytical applications of these methods. Raman spectra are useful for studying both the association of ions in clusters and the hydration sphere surrounding the ions. Raman spectra of HAN solutions show concentration-dependent center-frequency and line-width changes similar to those of alkali metal nitrates, but they are different from those of ammonium nitrate [284]. There is no substantial ion pairing in HAN at 0.2M. Markedly different Raman spectra are obtained for solid HAN: The line width decreases, and some bands split. The center frequency of the Raman band in solid HAN is temperature dependent. Raman spectra of XM46 are discussed in *Encyclopedia of Monopropellants*. These XM46 studies often include neat HAN as a baseline.

Slow reactions during the decomposition of 11-M HAN at ambient pressure and at very high pressures were followed by recording the Raman spectra of the solutions [285–287]. The Raman spectra of pure ammonium nitrate were included for comparison. The Raman spectra of an 11-M HAN solution at ambient and unconfined conditions and at elevated pressures were measured using a diamond anvil cell. An Ar^+ laser was used as the radiation source. The 5145 Å line was selected, and the power contained in this line was initially kept at 400 mW, but soon it became apparent that high-intensity laser light caused premature decomposition of the sample, and the beam

was attenuated with neutral density filters to about 10 mW. The pressure in the cell was determined by the pressure shift of the ruby 14405 cm^{-1} line of a ruby chip that was immersed in the sample. Pressure and temperature of the cell were varied over the range of 2–7 kbar and 295–393 K (22–120 °C). At pressures near 6 kbar and temperatures near 363 K (90 °C), a significant and irreversible change in the HAN spectra was observed. This change was interpreted as the result of thermal decomposition occurring within the sample, accompanied by the disappearance of features related to HAN nitrogen–oxygen bonds. Evidence of nitrous oxide formation was found, and some of the nitrous oxide appeared to be present in the solid state at very high pressures. A transient appearance of nitrogen dioxide in an early reaction stage was difficult to verify. Dehydration of HAN-H₂O samples was attempted by evacuating the chamber to approximately 0.1 mm Hg. Raman spectra taken before and after dehydration are shown in Figure 31, together with an H₂O spectrum.

Figure 31: Raman spectra of hydroxylammonium nitrate at ambient pressure conditions. (Reproduced and modified from [287].)

Legend: (a) 50% HAN-H₂O mixture; (b) dehydrated sample; (c) H₂O

The peaks at 3200 and 3430 cm^{-1} and the shoulder at 3600 cm^{-1} diminished as the result of the water being pumping off. The peaks at 3200 and 3430 cm^{-1} and the shoulder at 3600 cm^{-1} have predominant contributions from H_2O , and these features are assigned to the OH stretch mode. The vibration assignments of Raman frequencies are given in Table 23.

Table 23: Assignments for the Raman spectrum of an 11-M HAN- H_2O solution.

Wave number, cm^{-1}	Assignment
730	NO_3^- deformation
1010	N—OH stretching
1050	NO_3^- symmetric stretch
1190	OH bending (from HAN), NH_3 rocking
1420	Asymmetric NO_3^- stretching
1620	NH_3 deformation
2730	NH_3 , rocking and deformation (overtones)
3000	NH_3 N—H stretching
3200	O—H stretching (from both HAN and H_2O)
3430	O—H stretching (from H_2O)
3600	O—H stretching (from H_2O)

Data source: [286]

For comparison, very concentrated aqueous metal nitrate salt solutions were also investigated at high temperature and pressure by Raman spectroscopy to gain an understanding of the properties of NO_3^- under conditions similar to those observed in HAN [288].

3.3.10 Nuclear Magnetic Resonance Spectra of HAN Solutions

HAN concentrations in water were analyzed by H-NMR spectroscopy based on a linear relationship between the normalized chemical shift and the HAN concentration in water, combined with a rapid single-peak scanning method [289].

3.3.11 Electrical Properties of Hydroxylammonium Nitrate

3.3.11.1 Electrical Conductivity of Hydroxylammonium Nitrate Solutions

The electrical conductivity of HAN solutions and propellants based on HAN is an important parameter in the design of electric igniters in rockets and liquid-propellant guns. Ignition may not be due to simple ohmic heating or arcing but may also involve electrolysis and creation of a path of least resistance between the electrodes. Ion mo-

bility also plays a role in the corrosion of metals in HAN solutions, in particular if two different metals are in contact and form a galvanic element. HAN solutions and HAN-based propellants are good electrolytes. The equivalent conductance of HAN solutions has been measured and fitted to the Wishaw-Stokes equation to determine the limiting equivalent conductance and the distance of closest approach for the ions. The electrical conductance of aqueous HAN solutions is similar to that of solutions of monovalent salts.

See also [243, 244]. Those reports contain a very educational introduction to the behavior of ions in dilute and concentrated solutions of weak and strong electrolytes and helps to explain some of the unusual electrolytic behavior observed with HAN solutions. In particular, the importance of ion pair formation to solution behavior is discussed.

Figure 32 shows the specific conductance of HAN solutions as a function of HAN concentration between 0.1 and 13 M at three different temperatures. Kappenstein, Pillet, and Melchior [235] have taken the same data and smoothed the curve connecting the data points.

Figure 32: Specific conductance of HAN solutions at -12, +20, and +40 °C. (Reproduced and modified from [244].)

The equivalent conductance of aqueous HAN has been fitted to a Wishaw-Stokes equation to determine the limiting equivalent conductance and the distance of closest approach to the ions. The specific conductance of 11-M HAN as a function of temperature has been fitted to a general third-order polynomial equation. The electrical conductance of aqueous HAN solutions is qualitatively similar to other aqueous solutions of monovalent salts [290].

The specific conductance of HAN solutions in comparison to that of NaNO_3 solutions is shown in Figure 33. The two electrolytes behave very similarly. Sodium nitrate is much less soluble in water than HAN; therefore, the curve goes up to only 8 M.

Figure 33: Specific conductance of HAN solutions. (Reproduced and modified from [244].)

The electrical conductivity of 11-M HAN (75 mass-% HAN) solutions as a function of temperature was plotted and curve-fitted, as shown in Figure 34 [235].

Figure 34: Specific conductance of 11-M HAN as a function of temperature. (Reproduced and modified from [235].)

If the logarithm of the specific conductance λ (units of $\Omega^{-1} \text{ cm}^{-1}$) is plotted against the reciprocal reduced temperature, as shown in Figure 35, one obtains a straight line that is easy to express as a linear function:

$$\ln \lambda = 1.2319 - 423.08x \quad x = 1/(T - T_0) \quad T_0 = 162 \text{ K}$$

Table 24 gives the specific conductance of 11-M HAN solutions as a function of temperature [291].

Table 25 gives the specific and equivalent conductance of aqueous HAN as a function of concentration at three different temperatures.

Electrical conductivity is dependent on the frequency of the alternating current applied. If the frequency is too high, the electrons and ions have a hard time following the rapidly changing electrostatic fields. Measuring electrical conductivity as a function of frequency gives information on the rate of proton transfer and protonation/deprotonation (Table 26).

The electric conductivity of HAN solutions is a key parameter when studying the electrolytic ignition of HAN solutions (no fuel added) in an effort to better understand the electric ignition of HAN/fuel/water propellants [292]. See also [293].

The electric conductivity and electrolytic decomposition of aqueous HAN solutions of various densities were measured as a function of density [294]. The conductivity of aqueous HAN solution had a maximum value of $\sim 57.9\text{ mS/cm}$ at a density of $\sim 1.4\text{ g/cm}^3$. The conductivity decreased at higher concentrations above 1.4 g/cm^3 . In the electrolysis experiments, liquid- and gas-phase temperatures, current, and voltage time history were recorded. It was noted that there are three electrolytic decomposition reaction patterns for HAN aqueous solution, depending on the density/concentration, which can be further correlated with the conductivity of the solution.

3.4 Chemical Properties of Hydroxylammonium Nitrate

3.4.1 Reactions of Hydroxylammonium Nitrate

3.4.1.1 Solvate Formation

Hydroxylammonium nitrate forms solvate complexes with hydroxylamine free base, similar to such complexes formed with hydroxylammonium perchlorate and hydroxylamine. Regardless of an excess of hydroxylamine free base offered, HAN forms a monoligand complex with only one mol of hydroxylamine in its solvate sphere $[\text{NH}_3\text{OH}][\text{NO}_3] \cdot \text{NH}_2\text{OH}$ [295]. Such compound formation should be evident in the melting-point phase diagram of the $\text{NH}_3\text{OHNO}_3/\text{NH}_2\text{OH}$ system. However, HAN/HA mixtures are detonable and extremely shock sensitive [296].

3.4.1.2 Redox Reactions with Hydroxylammonium Nitrate

Hydroxylammonium ion, regardless of the anion it is paired with, is a reducing agent. The reducing potential depends on the pH of the solution and is strongest if the solution is allowed to become caustic, which would liberate some hydroxylamine as the free base. Redox reactions of hydroxylammonium salts, including HAN, are of interest as analytical methods and for the disposal of surplus HAN. Redox reactions catalyzed by traces of transition metals may be responsible for the limited storage stability of HAN-based rocket propellants. The most commonly encountered contaminant metal ion is iron in its trivalent state as Fe^{3+} . Iron in both states of oxidation forms complexes with hydroxylamine, hydroxylammonium, and many other nitrogen bases. The working principle of stabilizers such as α, α' -dipyridyl is based on the formation of such complexes.

3.4.2 Decomposition of Hydroxylammonium Nitrate

Hydroxylammonium nitrate decomposition can occur in the solid, molten, or sublimed state or in solution. The exact mechanism of decomposition of HAN by itself and in the presence of water-soluble fuels commonly used in monopropellants has been the subject of numerous studies, which we will try to organize, summarize, and critique here. The decomposition of HAN, HAN solutions, and HAN-based liquid gun propellants received a substantial amount of investigation during the decades when the RLPGs were in development. This area of scientific inquiry has benefited substantially from the sponsorship of the U.S. Army in its effort to develop a safe and stable liquid gun propellant. The objective of these studies was to determine at which temperature HAN starts to decompose, what the activation energies of the various individual steps of the global reaction are, which intermediates are involved, and what the products of reaction are. In addition, interactions of decomposing HAN with fuels had to be studied. The objective of these studies and the reason for including them here in detail was to prevent premature, unintended decomposition of HAN during storage and heat soak-back after firing of a gun and to achieve more reproducible, on-

command controlled decomposition in a gun or rocket engine. The presence of a fuel in formulated liquid gun propellants did not change the onset of thermal decomposition significantly. One would want to have a complete understanding of the decomposition of HAN by itself (in solution) before starting to examine HAN/fuel blends. The information gained in the past during the development of RLPGs is useful now in evaluating HAN-based monopropellants for applications in rocket propulsion systems.

In addition to decomposition of HAN in guns and rocket engines, there is also a substantial amount of interest in the decomposition of HAN under the conditions of the Purex nuclear fuel element reprocessing process, where it is used as a reductant and complexing agent. Inadvertent HAN solution decomposition during storage was the cause of accidental spills at uranium/plutonium process plants (Section 3.10.3).

The mechanisms of HAN decomposition in the solid and molten states and in concentrated solution are very similar. The decomposition in dilute solutions will result in somewhat different reaction-product compositions. Either condition, molten or dissolved, is affected by the presence of contaminants and catalysts. We will discuss the decomposition of solid or molten HAN first, followed by discussion of the decomposition of HAN in solutions.

3.4.2.1 Slow Thermal Decomposition of Molten HAN

DTA tests with 2–3-mg samples of HAN at a heating rate of 0.17 K/s showed a melting endotherm at 315.4 K and two exotherms at 487.1 and 495.6 K, as shown in Figure 36 [217]. The heat of reaction was 1226 kJ/kg.

Figure 36: DTA and TGA of solid HAN under He at 101 kPa. (From [217], reprinted and modified by permission of American Institute of Aeronautics and Astronautics, Inc.; permission conveyed through Copyright Clearance Center, Inc.)

The stability of HAN-based liquid propellants and the destabilizing effects of metal impurities were investigated using a DSC thermal stability test [215]. The test involved simultaneous ignition temperature (T_{ig}) measurements for eight samples (2.3 mg each) heated in glass capillaries in a DSC pressurized to 6.9 MPa (1000 psi). Baseline data were for neat propellant LP1845 as well as for samples of propellant “doped” with 3–150 ppm of Fe^{2+} or Cu^{2+} . The results showed that 5 or 10 ppm of either metal leads to a measurable decrease in T_{ig} and that the decrease in T_{ig} per unit metal concentration is greatest at the lowest metal concentrations. From the exo/endo nature and shapes of the DSC peaks under different conditions, it was concluded that when water vaporization was suppressed, there were no detectable endotherms or exotherms prior to ignition and that the first gas-producing reaction was apparently endothermic. When water vaporization was suppressed, the T_{ig} measurements for HAN-based propellants were much higher ($>473\text{ K} = >200^\circ\text{C}$) than previously suspected.

3.4.2.2 Reaction Mechanisms of Thermal Decomposition of Molten HAN

There are several possible overall reactions by which HAN can decompose. All include nitrogen and water as the reaction products, but they vary in the ratio of N_2O to HNO_3 formed:

The process described in reaction (5) is the one proposed by Klein in 1983 [297]. The process described in reaction (4) is the one proposed by Klein in a later study [298]. None of these equations accurately represents the stoichiometry of HAN decomposition. The ratio of decomposition products depends on the conditions of the experiment (temperature, pressure, catalysts, solvents). Several investigators have attempted to identify the main path of decomposition by analyzing the products formed, by looking for intermediates in the decomposition reaction, and by timing the rates at which the various products formed and the HAN disappeared. They also gathered evidence that certain catalytically active contaminants may steer the decomposition process in different directions from that typical for an uncontaminated sample.

The dissertation by Lee [299] contains a very good summary of theories developed by other investigators up to that time. The two main theories are those by Klein and those by Oxley and Brower. Klein suggested gaseous species formation by the reac-

tions among NH_3OH^+ , HONO , and HNO . Oxley and Brower proposed HONO and HNO reactions with the NH_2OH intermediate as the cause for formation of gaseous products such as N_2O , N_2 , and H_2O . Lee attempted to clarify these reactions by analyzing the time-resolved sequences of decomposition products of flash-heated samples using FTIR spectroscopy (Section 3.4.2.5).

Reaction Mechanism Proposed by Klein

One of the possible sequence of reactions in the thermal decomposition of HAN is described as follows [298, 300]: The initial dissociation is that of a portion of all HAN (in reversal of its formation by neutralization) into free hydroxylamine base and nitric acid:

This is an equilibrium reaction determined by the basicity (proton affinity) of the free base. In the presence of water-absorbing media, some of the nitric acid forms hydroxyl ions and nitronium ions:

Another first-step possibility is a proton transfer from $[\text{H}_3\text{N}^+\text{OH}]$ to $[\text{NO}_3^-]$, leaving the free base in the form of its isomer and tautomer, ammonia oxide H_3NO :

Proton-transfer reactions are generally faster than reactions involving larger ions. The unstable intermediate ammonia oxide was not characterized until recently, when its role in several industrial accidents caused by explosion of hydroxylamine free base was more closely examined; see Section 1.3.5 (free hydroxylamine base). Most of the references quoted in that section dealing with ammonia oxide are less than ten years old. Ammonia oxide is thermodynamically less stable than its tautomer, hydroxylamine, and will quickly rearrange itself to hydroxylamine:

This rearrangement will take place readily only if the molecule is unrestrained and out in the vapor phase by itself. In a strongly hydrogen-bonded cluster, ammonia oxide will survive longer, long enough to undergo an alternate reaction path: A hypothesized (but unproven) hydride ion transfer within the ion cluster with water elimination may lead to nitrous acid HNO_2 and nitroxyl $\text{HN}=\text{O}$:

or

Oxidation states of the nitrogen atoms on the reactant side are ammonia oxide N^{-1} and nitronium N^{+5} , and on the product side the oxidation states of the nitrogen atom are nitroxyl N^{+1} and nitrous acid N^{+3} . This information helps in balancing these redox reactions. Both HN=O and HNO_2 will react with HAN. The reaction of HNO_2 with any amine is a nitrosation, producing HO-NH-N=O , the tautomer of hyponitrous acid,

which decomposes to N_2O :

H-N=O could either dimerize and follow the same path, or it could react with $\text{H}_3\text{N}^+\text{OH}$

If both HO-N=O and H-N=O reacted with HAN at the same rate, equimolar yields of N_2O and N_2 would be obtained, but that is not the case. Reduction of nitrate ion by nitroxyl

is assumed to proceed at a rate similar to that of the reaction of HAN and nitroxyl, so that slightly more than half of the nitroxyl will be removed by reaction with nitrate. The nitrous acid formed in the latter reaction will then react with more HAN. The overall stoichiometry would be close to

which is the mechanism proposed by Klein in 1990. Salts of hyponitrous acid are stable, but nitroxyl and its dimer (hyponitrous acid) are unstable and rarely identifiable as intermediates. Nevertheless, many investigators have studied the reaction of hydroxylamine with nitric acid and nitrous acid, and all assume hyponitrous acid as an intermediate [301, 302]. It was suggested that the white fog forming above decomposing hot concentrated HAN solutions just prior to a fume-off consists of hyponitrous acid. This would merit additional investigation. A number of variables affect the overall stability of HAN. The effect of these variables on the chemistry of the system is diverse, and the level of control required to produce and maintain stable propellant is, by extension, also diverse. Variables with a significant effect on reaction rates and pathways are acid concentration and transition-metals content.

Reaction Mechanism Proposed by Oxley and Brower

Decomposition of dry HAN resulted in a gas mixture of 83% N₂O and 17% N₂ [303]. This ratio of decomposition products can be explained by the following schematic:

which is essentially the same as

Some NO₂ started appearing only toward the end of the reaction. An alternative, less probable scheme was proposed that involves a hydride transfer step and the formation of hydrazoic acid as an intermediate. An isotope-labeling study starting with ¹⁵NH₃OH⁺ NO₃[−] resulted in equal proportions of ¹⁴N¹⁵NO and ¹⁵N¹⁴NO, indicating that the proton exchange is rapid. It was also attempted to explain the mechanism by adding either ammonium nitrate or hydrazinium(1+) nitrate or hydrazinium(2+) dinitrate to the HAN melt. Although AN by itself does not decompose at 403 K (130 °C), it started to decompose to nitrogen while in a mixture with HAN at 403 K (130 °C). An experiment with ¹⁵NH₄NO₃ showed that NH₄⁺ is exclusively converted to N₂. Hydrazinium(1+) nitrate addition extended the induction period, but hydrazinium(2+) dinitrate shortened it. In both cases, hydrazoic acid was observed in the decomposition products.

3.4.2.3 Experimental HAN Decomposition Studies

Slow reactions during the decomposition of 11-M HAN at ambient pressure and at very high pressures were followed by recording the Raman spectra of the solutions [286, 287, 304]. Pressure and temperature of a HAN sample in a diamond anvil cell were varied over the range of 2–7 kbar and 295–393 K (22 to 120 °C). At pressures near 6 kbar and temperatures near 363 K (90 °C), a significant and irreversible change in the HAN spectra was observed, indicating incipient decomposition.

Hydroxylammonium nitrate and hydrazinium nitrate (HN) are both solids at room temperature, but a mixture of 50% HAN and 50% HN is a liquid at room temperature. Similar to the decomposition of HAN, HNO₃ is observed at about 373 K (100 °C) when this mixture is heated. Ammonium nitrate is indicated in the vapor phase beginning at 503 K (230 °C). At about 525 K (250 °C), another endotherm is observed where HN begins to decompose into HN₃ and other products. Nowhere along this path are there any exotherms.

A very thorough study of the molten HAN decomposition reactions and the reactions of HAN with nitrous acid and nitric acid was performed as part of a PhD dissertation [299]. See also [305, 306]. The apparatus consisted of two resistance-heated pre-heated copper rods with flat ends sequentially moving toward each other and trapping the sample in the middle, allowing a 300- μm gap for the gases to escape to the adjacent FTIR spectrometer. The spectrometer had a time resolution of 0.044 s and a wave number resolution of 1.29 cm^{-1} . Five-milligram (8 μL) samples of XM46, solid TEAN, 13-M HAN, and solid HAN were tested in the apparatus. The evolved species profile was typically recorded for 5 s for up to six species simultaneously. A typical results chart is shown in Figure 37.

Figure 37: Time-resolved evolution of decomposition products from 13-M HAN at 453 K (180 °C). (Reproduced and modified from [299] with permission by Dr. Hyung Sik Lee granted 14 February 2021.)

The pre-set heater temperatures were selected between 433 and 573 K (160 and 300 °C) in 20° increments. The induction times were plotted against the reciprocal absolute temperature to obtain activation energy data. The two induction time curves for 9-M HAN and XM46 were very similar. The induction times of solid HAN were longer than those of HAN solutions at 393 and 413 K (120 and 140 °C), but they were shorter at 433 and 453 K (160 and 180 °C). For solid HAN, N₂O was the dominant species formed, and HNO₃ concentration was somewhat higher than that in solution at the same temperature.

The thermal decomposition of HAN at pressures between 2 μm Hg and 50 μm Hg was studied using residual gas analysis tracing the production of nitrous oxide (N₂O), nitrosamide (H₂NNO), and nitroxyl (HNO) [307]. Initial expectation was that NO and NO₂ would be the primary species producing signals at 30 and 46 m/z, respectively.

Kinetic modeling studies of HAN solution, however, attributed these signals to HNO and H₂NNO, respectively. Thermal decomposition was achieved by injecting an aqueous HAN solution into a flowing thermal capillary and detecting the gas products with mass spectrometry. The results indicated that the formation of N₂O, H₂NNO, and HNO occurs not only in the bulk solution but possibly also on the surface of the aqueous HAN solution and in the vapor phase immediately above the solution surface.

The thermal and catalytic decomposition of aqueous HAN solutions was studied using TGA, DSC, and mass spectrometry [308]. The tests were conducted at heating rates of 1, 2.5, 5, and 10 K/min. The values of the apparent activation energy obtained for thermal decomposition using TGA and DSC were 62.2 ± 3.7 and 57.5 ± 3.5 kJ/mol, respectively, and they were in agreement with the literature data for solid HAN and solutions with high concentrations of HAN. The obtained values of the pre-exponential factor, 2.24×10^4 s⁻¹ for TGA and 3.55×10^3 s⁻¹ for DSC, were lower by six to seven orders of magnitude than those reported in the literature for aqueous HAN solutions, apparently because of full vaporization of water from the HAN solutions at the beginning of the TGA and DSC tests. The use of an iridium/rhodium foam catalyst decreased the temperature of complete decomposition by over 60 °C. The value of the apparent activation energy obtained for the catalytic decomposition using TGA was 63.9 ± 2.5 kJ/mol, and the value of the pre-exponential factor was 3.31×10^5 s⁻¹. Similar tests were also conducted at high pressures [309]. The onset temperature of thermal decomposition of HAN decreased by about 50 °C with increasing pressure from atmospheric to 2 MPa and remained virtually constant with further pressure increase to 15 MPa [310].

3.4.2.4 Computational HAN Decomposition Studies

The following eight reactions were chosen as the reduced reaction model for HAN decomposition [299]:

Except for reactions (4) and (6), these reactions are the same as in the mechanism proposed by Oxley and Brower. Preexponential factors and activation energies (from the literature) for the various steps were combined in a kinetic model that somewhat

reproduced the species evolution curves. Along with the reaction between NH_2OH and HONO , the dimerization of HNO is another probable pathway of N_2O formation:

HAN decomposition was studied at very high pressures using confined rapid thermolysis/FTIR spectroscopy over temperatures ranging from 423 to 498 K (140 to 225 °C) and pressures of 0–6.8 MPa (0–1000 psig) [311]. Results showed that the detected major IR-active species in the gas phase of HAN dissolved in water and solid HAN were H_2O , N_2O , NO , NO_2 , and HNO_3 . For solid HAN, H_2O is also the dominant species formed. The sequence of species evolution at atmospheric pressure show a three-stage process: **(1)** proton transfer, which reveals the presence of HNO_3 in the gas phase, **(2)** an induction period involving the rapid formation of nitroxyl and nitrous acid, which subsequently produces N_2O , and **(3)** a delayed evolution of NO_2 , suggesting the presence of competing autocatalytic processes involving HNO_2 . However, as pressure increased, the liquid-to-gas conversion rates also increased, revealing a fourth stage of the decomposition process in which the extent of conversion of the sample into gaseous products was larger, and NO_2 evolution was no longer delayed. Most important and surprising is the role of water in initiating the overall decomposition process of HAN: In experiments with dry, solid HAN, the induction times were typically longer than those conducted with either 9, 10.7, or 13-M HAN. Hence, water appears to play a significant role in altering the molecular structure of the liquid, which affects the proton-transfer process.

It was attempted to reproduce the sequence and ratios of decomposition product formation during thermolysis of solid HAN and HAN solutions by developing a kinetic model [312]. That model would be composed of interrelated individual reaction steps that work simultaneously to result in the global reaction rate, the one that is easiest to measure. The objective of this study was to propose a reduced model for the condensed-phase reactions of HAN and to determine accompanying Arrhenius-type rate coefficients. For this inverse-based analysis, two kinds of input data were used, measured gas-phase concentrations and the condensed-phase reaction temperatures. The experimental decomposition process was modeled by applying species conservation equations to the condensed-phase and the gas-phase regions separately. The experimental data that were used to deduce the rate coefficient parameters were the gas-phase species concentrations observed during thermal decomposition of 13-M HAN, including HNO_3 , N_2O , NO , and NO_2 [313, 314]. With the best-fit rate constants of the reaction model, the species evolution profiles of 13-M HAN were reasonably recovered, and the condensed-phase mass fractions were predicted. The reaction model, based on the eight reactions shown previously, was applied to the simulation of the species evolutions for solid HAN and HAN-water solutions including 10.7 and 9-M HAN. The simulated, predicted gas-phase concentrations coincided well with the measured data, indicating that the proposed global reaction mechanism captured most of the key reactions of HAN. A major unknown is how much of the gaseous products re-

main dissolved in the condensed phase of reaction products, but their mol fractions should be less than 0.1. See also [315].

Decomposition pathways for aqueous HAN solutions were examined by quantum mechanical molecular orbital computations using a DFT method [316]. Optimized structures were obtained for the reactants, products, and transition states, and the total electron energies of these structures were calculated. Energy barriers in the forward reaction and total energy release were calculated for 42 reactions that can participate in HAN decomposition, also including two self-decomposition mechanisms for HNO_3 . Potential energy diagrams for 20 different reactions were shown to illustrate the energy barriers. In the initial decomposition, the ion + neutral $\text{NH}_3\text{OH} + \text{HNO}_3$ reaction, the neutral + neutral $\text{H}_3\text{NO} + \text{HNO}_3$ reaction, and the HNO_3 self-decomposition pathways were all found to have reasonable energy barriers, with values of 91.7, 88.7, and 89.8 kJ/mol, respectively. The overall reaction resulting from any of these pathways can be written as

The ionic reaction is dominant during the initial decomposition of HAN in aqueous solution because $\text{H}_3\text{N}^+\text{OH}$ and NO_3^- are the major species in such solutions. The investigators examined six mechanisms, and each of these schemes provided the same global reaction:

It was concluded that the ion + neutral $\text{H}_3\text{N}^+\text{OH} + \text{HNO}_3$ reaction mechanism is dominant during the initial HAN decomposition in aqueous solution. The associated energy barrier of 91.7 kJ/mol was in good agreement with the activation energy reported in a previous study.

A mechanism for the radical reactions of HAN in the aqueous phase was identified and investigated using *ab initio* computations [317]. Optimized structures for the reactants, products, and transition states were obtained, and the total electron energies of such structures were calculated. The cleavage of HNO_3

was found to trigger the radical reaction. The $\text{H}^\bullet$ abstraction reactions

and other reactions, including decomposition of HONO and HNO, were investigated using *ab initio* computations. HAN has a high reactivity and ignitability compared to AN. $\text{H}^\bullet$ abstraction from NH_2OH has a considerably lower barrier than the one from NH_3 . The differences in reactivity of NH_3 and NH_2OH is the cause of the differences in thermal stability of AN and HAN. The initial reaction that triggers this mechanism had the highest energy barrier (205.0 kJ/mol) of all the reactions investigated in this work. It was concluded that the homolytic cleavage of HNO_3 is the rate-determining step for the decomposition of aqueous HAN solution.

The thermal stability and kinetics of HAN decomposition were studied using DSC, and the thermal decomposition reaction mechanism was modeled using quantum mechanical molecular orbital DFT methods [318]. With the help of parameter values from the non-isothermal DSC curves of HAN, the thermal decomposition activation energies and pre-exponential factors were obtained by the Kissinger and Ozawa methods. The calculated results showed that the values of the activation energy calculated using the Kissinger and Ozawa methods were 67.9 and 70.4 kJ/mol, respectively. The most probable mechanism function was then calculated using the Satava-Sestak method. Seven different paths for the thermal decomposition mechanism of HAN were formulated, and DFT was used to carry out a dynamics analysis for each of these. The seven mechanisms were ranked in the order from the most probable to the least probable mechanism.

A detailed mechanism was developed for thermal decomposition of HAN solutions, based on quantum mechanical calculations using the SMD-B97X-D method [319]. The mechanism described multiple kinetic processes, including nitration and nitrosation of hydroxylamine, HNO dimerization, and HONO-regeneration pathways involving H-abstraction reactions. Rate constants of elementary reactions were estimated using transition state theory with consideration of diffusion effects of all species involved. Kinetic modeling was performed to predict species concentration profiles in 0.1-M HAN in the temperature range of 463–523 K. Results showed reasonable agreement with the experimental data from flow reactor studies. For more concentrated solutions, strong autocatalytic behaviors were predicted with the late emergence of NO_2 and HONO, whose regeneration was considered as the major autocatalytic pathway. Sensitivity analysis results suggested an acid-catalyzed nitration-nitrosation pathway, based on which the autocatalysis should be caused by the rise of solution acidity. A linear correlation can be observed in the previously reported apparent Arrhenius parameters, which may be reconciled via a kinetic compensation effect.

A ReaxFF reactive force field set has been developed for reactive molecular dynamics simulations of the thermal decomposition of HAN [320]. The training set consists of geometries, partial atomic charges, and energy barriers for a number of reactions that participate in HAN thermal decomposition. Geometries and partial atomic charges were calculated in both the gas phase and in solution. The SMD-GIL solvent

model was used to approximate concentrations of HAN in solution and the rate of their change. Transition states for elementary reactions were found at the GIL level of theory. An important autocatalytic pathway for the regeneration of HONO in HAN decomposition was identified. The set from this work can be used to train a ReaxFF force field capable of conducting reactive molecular dynamics simulations of HAN thermal decomposition.

A detailed chemical kinetics model for the liquid-phase reactions of aqueous HAN, based on quantum chemistry calculations, included thermal corrections, formation enthalpies, entropies, and heat capacities of chemical species that were calculated from the partition functions using statistical machinery [321]. Reaction-rate coefficients were determined to allow the application of transition state theory and variational transition state theory to reactions identified in previous studies. Thermal and evolved gas analyses were conducted for 92 mass-% aqueous HAN solution under specific heating conditions. The heat of reaction was measured using a heat flux calorimeter that allowed accurate and reproducible calorimetric measurements with a sensitivity of 5–10 μ W. In each trial, a ~20-mg sample was placed in a glass vial within a high-pressure stainless steel chamber, after which the chamber was purged with argon and sealed. Maximum heat flow occurred at 424 K (151 °C). In addition, a DTA-TGA instrument was connected to a mass spectrometer to analyze the gases formed during decomposition. The new model with 92 reactions had the ability to simulate the thermal decomposition of such a solution, and it successfully predicted the heat of reaction and the gases that result from decomposition under these conditions. This kinetics model also provided a kinetic mechanism for the decomposition of HAN. In this mechanism, the initial reaction

triggers the overall decomposition, while the subsequent reactions

and

are exothermic and accelerate the decomposition. This mechanism can be summarized by the global one-step reaction

3.4.2.5 Rapid Decomposition of HAN

The species that evolve during rapid thermolysis of solid HAN were analyzed by rapid-scanning FTIR spectrometry, with a complete scan performed every 100 ms [266]. This combination of DTA and product analysis is a good method to “unravel” an energetic

molecule step by step and to identify the weak links in a molecule where the reaction starts first. The rapid thermolysis of solid HAN at a heating rate of 35 K/s under 0.69 MPa (100 psi) argon showed nitric acid, followed by N_2O and NO_2 .

A similar test [322] with 2-mg samples at a heating rate of 100 K/s under 3.44 MPa (500 psi) argon also showed nitric acid first, followed by N_2O and NO_2 and water. The initial endotherm at 353 K (80 °C) leads to proton transfer and release of HNO_3 . A strong exotherm follows, starting at 373 K (100 °C). HAN is the only compound that shows oscillations in the rate of gas evolution during the exotherm. At pressures above 690 kPa (100 psi), the concentrations of the emerging products oscillate during the first few seconds of rapid thermolysis before dampening after 5 s.

3.4.3 Thermal Decomposition of Hydroxylammonium Nitrate Solutions

Based on t-jump FTIR spectrometry of intermediate species, several reaction pathways have been proposed. For instance, the nitronium ion and the hydroxide ion can be involved in the following reactions:

Once HONO and HNO build up in large concentrations, the induction period is near its completion, and NO and N_2O as well as water evolve into the gas-phase region and are detected by their IR absorption. The formation of these species could come from an HONO and HNO attack on HAN via the global steps

A model has been developed for the formation of ammonium nitrate in HAN-based propellants, such as XM46. The amount of ammonium nitrate in aged HAN is an indication of the past thermal history of the propellant.

The following is a summary of publications on HAN decomposition in aqueous solutions, arranged in chronological order.

In aqueous solutions, two reactions compete with each other, one in which nitrous acid is formed and one in which nitrous acid is consumed [323, 324]:

The former is dominant in low HA and high HNO_3 concentrations, and the latter is dominant at higher HA concentrations. The decomposition is characterized by an induction period that depends on the initial concentration of nitrous acid, total acidity, and other reactants present.

Hydroxylamine is oxidized by nitric acid to form nitrous oxide and nitrous acid, the proportions varying with reaction conditions [325]. The reaction is delayed by an induction period, followed by a rapid autocatalytic process. Addition of nitrite eliminates the induction period, while addition of nitrite scavengers completely prevents any reaction. Nitrous acid is an essential catalyst for the reaction, and the initial rate of reaction obeys the equation

$$\frac{d[\text{HNO}_2]}{dt} = K[\text{HNO}_2][\text{NH}_3\text{OH}^+].$$

Hydroxylammonium nitrite is a potential intermediate in the decomposition of HAN. If prepared by other means and isolated, it decomposes quickly [326]. Isotopic experiments using ^{15}N -enriched hydroxylamine showed that virtually all of the N_2O arose from reaction between HNO_2 and hydroxylamine. The mechanism suggested by Pembridge and Stedman [325] involves oxidation of unprotonated hydroxylamine by N_2O_4 to form the nitroxyl diradical HNO ; this is then further oxidized to HNO_2 , which reacts with hydroxylamine to form N_2O .

The yield of a minor product of the reaction between nitrous acid and hydroxylamine, *trans*-hyponitrous acid, has been studied over a wide range of conditions [327]. It has been shown that, for nitrosation of free hydroxylamine by four different neutral nitrosyl compounds, the yield varies with the nature of the reagent: ONBr 27%, ON-NCS 12%, ONNO_2 6%, and ONCl 15%. For nitrosation of the hydroxylammonium ion by the nitrous-acidium ion, the yield is only 2.0%.

Hydroxylammonium ion in HAN is subject to oxidation by both nitric and nitrous acid [328].

A very unusual phenomenon was observed in decomposing HAN solutions: An initially homogeneous solution of hydroxylamine in nitric acid can react to form a two-layer system, a layer of nitrous acid in nitric acid in the top above a layer of hydroxylamine in nitric acid below, with a sharp boundary between them that moves steadily downward as the reaction progresses autocatalytically [329, 330].

The intermediates during reaction of hydroxylamine with nitric acid can be identified by isotope labeling [331]. An isotopic study of the reaction of hydroxylamine with nitric acid showed that a symmetrical intermediate is involved in several steps of the reaction, probably *cis*-hyponitrous acid [332]. The results support a theory that the initial nitrosation is an electrophilic displacement of a proton rather than an addition reaction of the type thought to occur in diazotization and deamination. Hyponitrous acid is a very likely intermediate of HAN decomposition, and its potential formation has frequently been overlooked by other investigators.

A differential scanning calorimeter was modified for high-pressure operation up to 6.9 MPa (1000 psi), and samples of LP1845 and 13-M HAN were analyzed in aluminum and tantalum pans [333]. Tests with LGP1845 in aluminum pans at 6.9 MPa yielded an average $T_{(\text{in})}$ of 393 K (120 °C) with a standard deviation of ± 4 °C, while a higher average $T_{(\text{in})}$ of 397.9 K (124.8 °C) with a standard deviation of ± 2.4 °C was

obtained for 13-M HAN (without the addition of fuels) in the presumably more inert tantalum pans at a somewhat lower pressure (5.2 MPa).

Addition of hydrazinium(1+) nitrate to HAN suppressed the decomposition of HAN for several hours [334]. In one instance, a sharp explosion occurred at 413 K. Mass spectrometric analysis showed hydrazoic acid as the pyrolysis product, in particular if hydrazinium(2+) dinitrate instead of the (1+) salt was added to the HAN. The (2+) salt shortened the induction period and accelerated the decomposition reaction of HAN.

Two unusual phenomena, bistability and fluctuating, pulsating, and oscillating reaction rates occurring in the nitric acid–hydroxylamine continuous-flow stirred tank reactor system, were studied experimentally and theoretically to see how they relate to the decomposition of HAN during industrial uses of this chemical [335, 336]. Stationary concentrations in the stirred reactor were plotted vs. inlet concentrations to derive reaction mechanistic theories. Similar oscillations were observed in the oxidation of hydroxylamine by other oxidizers.

A computer model was developed to simulate the decomposition of 5.2 to 9.1-M HAN solutions [337]. This model can also be applied to deflagration of hydroxylammonium perchlorate. The theory considers the chemical kinetics, energetics, and fluid dynamics of the combustion zone, making use of asymptotic analysis to decide which combustion mechanisms are consistent with available data. The model is useful in conjunction with experimental results to obtain frequency factors and overall activation energies for HAN decomposition. Results suggested that deflagration rates are controlled by condensed-phase combustion, with production of water dominating the heat release, and that phase and chemical equilibrium are not approached in the condensed-phase combustion zone. The mass consumption rate of HAN was assumed to follow a zero-order expression, with an activation energy of about 63–73 kJ/mol (14.5–17 kcal/mol), which is close to that of proton transfer. These results support the postulate that the rate of HAN decomposition is controlled by the rate of proton transfer from NH_3OH^+ to NO_3^- .

In a later study at the University of Delaware, researchers used a Nd:YAG laser at 1.064 μm to excite Raman spectra of decomposing HAN solutions in a sapphire window flow-through cell at up to 500 K and 295 bar [338]. The exothermic decomposition of aqueous HAN solutions was investigated as a function of temperature, concentration, and flow rate. Rapid decomposition occurred as soon as the samples reached 460 K, causing a sharp drop of HAN concentration. From the induction times, apparent activation energies of 129 ± 29 and 66 ± 8 kJ/mol were estimated at HAN concentrations of 0.9–1.5 and 1.6–1.7 M, respectively. It was suggested that at low concentrations the decomposition proceeds via

whereas at higher concentrations (>1.52 M) the reaction

becomes more important. The overall reaction was proposed to be

Comparing the FT Raman spectra of samples before and after passing through the heated cell showed that the N—OH stretch of H_3NOH^+ was completely absent after reaction, whereas NO_3^- had been only partially consumed. N_2O was the only nitrogen-containing gaseous product. The decomposition of HAN is autocatalyzed by HNO_2 .

Using a similar flow-through cell but measuring IR absorption in an FTIR spectrometer instead of Raman excitation, the rate of decomposition of 0.1 to 0.2-M HAN solutions at 463–523 K and 27.5 MPa was measured and the intermediates identified [339]. The loss of NH_3OH^+ and the formation of N_2O occurred at the same rate under these conditions and could be fitted to a first-order rate expression. From the slope of the averaged NH_3OH^+ concentration and residence time curves, an activation energy of 103 ± 21 kJ/mol was derived. This is similar to the numbers obtained from the Raman spectra. See also [340].

The rapid thermolysis studies of HAN and other energetic materials were tested in a confined rapid thermolysis/FTIR apparatus using about 8 μL of a 13-M HAN solution at heating rates exceeding 1500 K/s to a set temperature (403 or 433 K), where decomposition occurred [313, 314]. The rapid heating was achieved as a result of confining the sample between two closely spaced isothermal surfaces instead of just placing it on a heated filament ribbon. The gaseous decomposition products (H_2O , N_2O , NO , HNO_3 , NO_2) departed from the confined space through a rectangular slit into the region that was traversed by the IR beam. The evolved gases were quantified using FTIR absorption spectroscopy. The results obtained in this study of the temporal evolution of species concentrations from these ingredients were in reasonably close agreement with results available in the literature. See also [341].

Binary aqueous HAN solutions of different concentrations (20, 60, and 83 mass-%) were thermally (and catalytically, see below) decomposed [221]. The initial reactions of HAN solutions are very similar to those of XM46 propellant. The thermal stability of HAN solutions was measured using a TGA and a DTA apparatus. The thermograms of HAN solutions with three different HAN concentrations are shown in Figure 38 and 39. The onset of exotherms shifts to lower temperatures for higher HAN concentrations.

Figure 40 is a similar set of data except that DTA and TGA are shown on a common time scale [342].

Hydroxylammonium nitrate is an important reagent used in the separation of plutonium and uranium in the Purex process for reprocessing spent nuclear reactor fuel rods. It is used to reduce the plutonium from Pu(IV) to Pu(III), causing a change in solubility and the transfer of the plutonium from an organic phase to an aqueous phase. The aqueous solution used in these separation systems is a concentrated nitric acid

Figure 38: Thermogravimetric analysis of HAN solutions. (Republished and modified from [221], with permission of © 2002 American Institute of Aeronautics and Astronautics, Inc.; permission conveyed through Copyright Clearance Center, Inc.)

solution containing hydroxylammonium ion, trace amounts of nitrous acid, and hydrazinium nitrate as a stabilizing agent. The nitrous acid is an impurity present in nitric acid solutions and acts as an unwanted catalyst in the oxidation of hydroxylamine by nitric acid. Any hydroxylamine that is unwittingly oxidized by nitric acid is lost for the Pu(IV) to Pu(III) conversion. In addition, azide formation is an unwanted byproduct. There have been incidents in which HAN solutions fumed off during storage, causing severe radioactive contamination of work areas.

Hydroxylamine can react autocatalytically with nitric and nitrous acids or act as a nitrous acid scavenger.

Under certain conditions, the combination of (R-1) and (R-2) can lead to rapid evolution of $\text{N}_2\text{O}(\text{G})$; this reaction has been blamed for several vessel ruptures at nuclear facilities. It was therefore of interest to find methods to predict the thermodynamic properties of the reactants and the heat of reaction. An improved understand-

ing of these reactions is needed to determine the “stability boundary of hydroxylamine” for safe operation of the plutonium–uranium reduction extraction (Purex) process.

Ab initio molecular orbital (MO) calculations were performed to develop an elementary reaction mechanism for the autocatalytic and scavenging reactions of hydroxylamine in aqueous nitric acid solutions similar to those used for the Purex process [343]. Under the operating conditions of the Purex process (6-M nitric acid), the reactive forms of hydroxylamine are NH_3OH^+ , a trace of NH_2OH , and the complex $\text{NH}_3\text{OH}\cdot\text{NO}_3$, and those of nitrous acid are NO^+ , H_2ONO^+ , N_2O_4 , N_2O_3 , NO_2 , and NO . It was found that in solutions the autocatalytic generation of nitrous acid proceeds through free radical pathways at low-hydroxylamine concentrations from unprotonated NH_2OH via hydrogen abstraction. At high $[\text{NH}_3\text{OH}^+]$, there is a possible involvement of the NH_3ONO^+ intermediate via the reaction

The NH_3ONO^+ intermediate, in turn, is formed via the ion–ion reactions of NH_3OH^+ with NO^+ and/or the reaction between NO^+ and HAN. The intermediates involved in the scavenging reaction of nitrous acid by hydroxylamine are NH_3ONO^+ , NH_2ONO , $\text{NH}_2(\text{NO})\text{O}$, $\text{NH}(\text{NO})\text{OH}$, and HONNOH , and the rate-determining step is the 1,2-NO migration in NH_2ONO leading to $\text{NH}_2(\text{NO})\text{O}$. Reactions

and

were also studied. The rate constants and activation energies for the key reactions were estimated from theoretical considerations.

In continuation of this work, *ab initio* MO calculations were performed and thermochemical parameters estimated for 46 species involved in the oxidation of hydroxylammonium ion in aqueous nitric acid solution [260]. Solution-phase properties were estimated by computational chemistry calculations for physical properties and constants in solution. Hydroxylammonium nitrate solutions will sustain thermal decomposition as long as the concentration is above 40% (5 M) and the pressure is above 5 MPa.

A mathematical model was developed that may be used to determine the safety of HAN solutions used in solvent extraction purification of plutonium [344]. The most significant hazard associated with hydroxylamine use in processing plutonium is its rapid, autocatalytic reaction with nitric acid, which can result in an explosion or pressurization of process vessels with spills of radioactive materials. In addition, heat is produced by the reaction that could potentially ignite organic process solvents.

The HAN decomposition reaction can occur only under specific process conditions (temperature; HAN, plutonium, and nitric acid concentrations), and the model was used to identify worst-case conditions so that they can be avoided. The kinetic model used all of the known significant reactions that could occur in process solutions containing HAN and nitric acid, as well as plutonium and iron. The reaction kinetics data (rate laws, rate constants, activation energies) used in the model were obtained from chemical literature sources. The model shows that the autocatalytic HAN reaction with nitric acid is very rapid and is catalyzed by Pu(III) and Fe(II) in process solutions. High temperatures and nitric acid concentrations also promote the reaction.

Hydroxylammonium nitrate is used to reduce Pu(IV) to Pu(III) in the separation of plutonium from uranium during reprocessing of spent nuclear reactor fuel elements. Hydroxylammonium nitrate becomes unstable under certain conditions and has been known to explode. It is necessary to deactivate HAN once the reduction of plutonium is finished. A report reviews what is known about the chemistry of HAN and various methods to achieve safe destruction of residual HAN in process effluents [345]. There are some areas where additional information is needed to make educated decisions about the handling of HAN in the reprocessing of nuclear fuel elements. Experiments have demonstrated a number of non-radiolytic ways to safely decompose unwanted HAN, including heating in excess HNO_3 , reaction with HNO_2 , photolytic oxidation in the presence of H_2O_2 , and the addition of redox oxidizer such as Fe(III) that will oxidize the hydroxylamine. The report confuses the reactivity of HAN with that of the free base HA, but the Purex process works exclusively in acidic solutions while the extraction with tributyl phosphate is taking place, and there should not be any free base present under those acidic conditions. The report fails to draw on the vast amount of information on HAN solution stability that was generated several decades ago when HAN-based propellants were being evaluated as liquid gun propellants.

3.4.3.1 Activation Energy of the Thermal Decomposition of Hydroxylammonium Nitrate

Several activation energy numbers have been mentioned in the preceding sections. Here we present a few more publications on the same subject. Earlier studies showed that hydroxylamine free base decomposition is well described by a first-order kinetics, with an overall activation energy of 29 kcal/mol [346].

The kinetics of thermal decomposition of molten HAN was measured by the rate of heat release under isothermal conditions in glass ampoules that were initially evacuated [347]. The bath temperatures were in the range of 358 to 394 K (84.8 to 120.9 °C). The decomposition of molten HAN proceeds faster and faster by autocatalysis, and at the point of about 60% decomposition it is 200–300 times faster than at the outset of

the experiment. For up to 60% decomposition, the rate increases with the square of the degree of decomposition η

$$\frac{d\eta}{dt} = k_1(1 - \eta) + k_2(1 - \eta)\eta^2$$

as long as $\eta < 0.6$. Past that point, the rate is less than to the power of two. k_1 is dependent on the loading density m/V . Its temperature dependence at $m/V = 0.0025 \text{ g/cm}^3$ is

$$k_1 = 4.2 \times 10^4 \exp[(- 16450 \pm 450)/RT]$$

The loading density of the ampoules was varied from 0.001 to 0.0027 g/cm^3 and has a distinct effect on the rate of decomposition. IR analysis of the decomposition products showed them to consist of NO_2 , NO , N_2O , and H_2O . The temperature dependence of the effective rate constant is

$$k_{\text{ef}} = 13.73 \exp[(- 15300 \pm 1800)/RT]$$

where k_{ef} is the rate constant in s^{-1} . The activation energy is $66 \pm 7.8 \text{ kJ/mol}$ ($15.3 \pm 1.8 \text{ kcal/mol}$). The heat of reaction at $\sim 373 \text{ K}$ is 1641 J/g (380 cal/g).

Addition of 5–20 mol-% HNO_3 resulted in vigorous decomposition of the salt even at room temperature. Addition of ammonia delayed the onset of the autodecomposition reaction. It was suggested that this indicates that the process occurs via the molecular forms of the initial base and acid formed by dissociation of the salt

and not through the ionic form because other hydroxylammonium salts decompose more slowly. The HAN decomposition reaction is second order with respect to nitric acid:

$$\frac{d[\text{NH}_3\text{OH}^+]}{dt} = -k[\text{NH}_3\text{OH}^+]_0 \times [\text{HNO}_3]_0^2$$

The fact that the reaction is second order with respect to HNO_3 at the initial stages of decomposition of the pure salt supports a hypothesis that there is interaction between NH_3OH^+ and N_2O_5 or the NO_2^+ nitronium cation.

Other reactions postulated to occur in the background during the decomposition of HAN include

but little proof was offered that they play an important role (if any) in the process.

An activation energy of 69.9 kJ/mol (16.7 kcal/mol) for decomposition of HAN solutions ranging from 5.2 to 9.2 M was calculated [337]. An activation energy for decomposition of solid HAN of 64 kJ/mol (15.3 kcal/mol) was proposed [348].

3.4.3.2 Catalytic Decomposition of Hydroxylammonium Nitrate Solutions

Although it is unlikely that HAN by itself will ever be used as a monopropellant, numerous studies have been conducted to find catalysts that will reproducibly and repeatedly initiate the decomposition of HAN solutions at room temperature, similar to the reaction of S-405 catalyst with hydrazine. Pre-decomposition of HAN prior to injection into a hybrid rocket engine would be a good application of HAN as an oxidizer. The hot, oxygen-rich exhaust from a HAN decomposition reactor might be hot enough to ignite a hybrid fuel grain or to ignite co-injected, otherwise non-hypergolic liquid fuels such as kerosene. Actually, testing catalysts with just HAN without dissolved organic fuels may have the advantage of the catalyst not being fouled by soot or other organic pyrolysis residues. The catalytic decomposition of HAN is a very important initial step in the application of HAN-based monopropellants in catalytic reactors, regardless of the type of fuel present. Many catalysts have been evaluated first with HAN by itself (typically using an 81% = 13-M HAN solution) and later with the actual fuel-containing monopropellant that is closer to the actual application; see *Encyclopedia of Monopropellants*.

The reactions discussed here are the same fundamental reactions that take place in HAN-based monopropellants in the presence of fuels. *Encyclopedia of Monopropellants*, chapter “Hydroxylammonium Nitrate-Based Monopropellants,” in this book series contains a discussion of catalysts for decomposition of HAN solutions not only by themselves but also in the presence of a fuel. Catalysts found to be active in the decomposition of HAN aqueous solutions in the absence of fuels would be equally active with HAN/water/fuel blends, maybe even more so [349]. In the current chapter we are summarizing catalyst studies applicable to HAN solutions, which would result in much lower combustion chamber temperatures than the decomposition of HAN monopropellants. To our knowledge, HAN solutions have never been used as a monopropellant by themselves without the addition of fuels in homogeneous or emulsified mixtures. Tests conducted with catalytic decomposition of HAN solutions by themselves are useful for the evaluation of catalysts for the decomposition of HAN/fuel solutions. They are safer to perform than tests with live monopropellants. There is usually a good correlation of relative activities of catalysts in tests of HAN solutions with and without added fuels.

It was hoped that addition of nanoparticles from TiO_2 or SiO_2 to HAN solutions would lower the decomposition onset temperature and accelerate the strand burning of HAN solutions and monopropellants based on HAN. Synchronized TGA and FTIR measurements were performed to analyze the decomposition characteristics of HAN aqueous solutions with suspended titanium dioxide (titania) nanoparticles [350]. The weight-loss rates as well as gas-generation rates of samples with various TiO_2

loadings in HAN aqueous solutions were measured to gain a better understanding of the influence of nanoparticles on the thermal decomposition of HAN-based propellants. Thermal decomposition tests were performed using a synchronized TGA-FTIR (PerkinElmer STA8000 and PerkinElmer, Spectrum Two). The sample weight loaded for each test was 10 ± 0.5 mg, and the sample was heated from 303 K (30 °C) to 573 K (300 °C) at 10 °C/min in the TGA-FTIR furnace. The purge gas was nitrogen. Resolution of the FTIR spectrum was a modest 4 cm^{-1} to allow higher sampling frequency of the decomposed gas. The onset of decomposition temperature was drastically reduced from 445 K (172 °C) to 393 K (120 °C) as the result of the addition of TiO_2 nanoparticles.

The catalytic decomposition of HAN solutions was investigated using a series of platinum and iridium catalysts supported on mesoporous materials such as MMZY, KIT-6, and SBA-15 [351]. A study of the effects of the active metal loading and the pore structure of the catalysts on decomposition of HAN solution showed that the activity of platinum catalysts supported on mesoporous material was superior to that of iridium catalysts on the same support. The Pt(10)/SBA-15 catalyst showed excellent decomposition activity and was the best among the catalysts tested, which was probably due to its favorable pore structure. Because the pore size of Pt(10)/SBA-15 is larger than that of Pt(10)/MMZY and Pt(10)/KIT-6, it is better for diffusion of reactants and product gases. The activity of the catalyst increased with the Pt active metal loading on the SBA-15 support.

Since most HAN-based monopropellants contain substantially more HAN than fuel, it is a valid assumption that any catalyst active in decomposing 13-M HAN will also be active in decomposing HAN/fuel blends.

It has been difficult enough to gain only a modest understanding of the homogeneous thermal decomposition of HAN solutions. Various theories have been proposed, and kinetic models have been developed to predict the rate of HAN decomposition. It was difficult to do this for a simple solution of HAN in water without any catalytic surfaces. It is considerably more difficult to develop a similar model for the decomposition of HAN solutions on the surfaces of catalysts. In addition to homogeneous liquid-phase reactions, surface-catalyzed and mass-transfer limited mechanisms come into play. Even if a working kinetic theory for one type of catalyst is developed, it will not automatically apply to other catalysts with different active metals.

The development of high-temperature, long-life, capable catalysts for use with HAN-based monopropellants in rocket engines is described in *Encyclopedia of Monopropellants*, chapter “Hydroxylammonium Nitrate-Based Monopropellants.”

HAN Decomposition in Batch Reactors

HAN decomposition in batch and dynamic flow reactors has been studied mostly in academic settings, with the intent of testing the same catalysts in rocket engines at a later time. Platinum catalysts supported on two types of silica-doped alumina carriers were compared for the decomposition of 79% HAN solutions in a TGA and

a closed-bomb microreactor [352, 353]. The supports were prepared by sol-gel synthesis (hydrolysis of alkoxyl aluminum and silicic acid ethyl ester) and dehydrated by subcritical drying (giving xerogels) or supercritical drying with CO_2 (giving aerogels). The 10% platinum was either coprecipitated with the hydroxides before the sol formation (a one-step procedure), or the granular carrier was impregnated with hexachloroplatinic acid solutions and reduced under hydrogen at 673 K (400 °C). The carrier was calcined in air for 5 h at 1473 K (1200 °C) prior to active metal deposition [354].

As an alternative method, the active phase was introduced by impregnation from aqueous platinum precursor solutions or by one-step addition of the precursor before the sol formation. The impregnated catalysts always displayed the best activity, which correlates with the smaller Pt crystallite size that they support. Aerogels have better thermal stability at high temperatures (1473 K = 1200 °C) and are more homogeneously dispersed than xerogels. In spite of this, aerogels were less efficient for the decomposition of HAN solutions at low temperatures. The one-step procedure led to an increase of the thermal stability for the aerogel samples, but the catalytic activity was less efficient. The impregnated catalysts always had the best activity (lowest exotherm in the DTA) in relation to the lower crystallite size of the metallic particles. One of the most important findings of this study was that aerogels can maintain high surface area at high temperatures. The other encouraging result was the possibility to decompose aqueous HAN solutions catalytically at low temperatures (less than 313 K = 40 °C) with a short ignition delay (less than 1 s). The best catalyst was a xerogel catalyst activated by impregnation. The onset of the exotherm of this catalyst in 79% HAN was 345 K (72 °C). After 15 injections of HAN solution into the batch reactor, the active metal content of all catalysts had dropped to half the original value. XRD and transmission electron microscopy (TEM) identified crystallite growth of the platinum crystallites. Active metal loss and crystallite growth combined to cause deactivation of the catalyst after a very short service life. See also [353, 355].

In order to supplement data obtained with the constant volume batch reactor, a dynamic laboratory reactor with online product mass spectrometric analysis was developed to study the thermal or catalytic decomposition of aqueous 20 and 80 mass-% HAN solutions [356]. This reactor allowed the evaluation of catalytic activity of different catalyst-propellant combinations, the qualitative and quantitative time-resolved determination of the reaction products, and control of the selectivity for the formation of nitrogen and nitrogen oxides (N_2O , NO, NO_2). It can be used in isothermal or increasing temperature modes. For dilute solutions (20 mass-% HAN), the thermal decomposition resulted in formation of mostly N_2 and NO as primary products, whereas nitrous oxide N_2O and nitrogen dioxide NO_2 were only formed later (secondary products). The thermal decomposition of concentrated mixtures (80 mass % HAN) gave first N_2 and O_2 during the thermal decomposition, NO being only a secondary product. On the contrary, NO appears to be a primary product in the presence of a catalyst, and NO_2 remains only a minor product (Figure 41 and 42).

In the downstream section of the dynamic flow reactor, a white powder had sublimed and deposited as a result of decomposing 80% HAN solutions. It was analyzed and found to be ammonium nitrate [357]. The analytical results were supplemented by analyzing the aqueous solutions collected from the condensate by Raman spectroscopy. Based on the species detected in the mass spectrogram, the equations in Table 27 were proposed to describe the decomposition of HAN.

Table 27: Balanced equations for decomposition reactions of HAN.

Data source: [357]

The formation of nitric acid leads to the highest energy release and would be thermodynamically favored. The balanced equation corresponding to the overall thermal decomposition process is a combination of equation 1 and equation 4 from Table 27:

The corresponding enthalpy of reaction is -119.8 kJ/mol. The experimentally obtained $\text{N}_2:\text{NO}:\text{N}_2\text{O}$ ratio was 6:2:2, and it agreed well with the ratio in the above equation. The results were compared to those obtained for ammonium nitrate and ammonium dinitramide decomposition. In both cases, nitric acid formation competes with oxygen formation. Based on equilibrium calculations using HSC Gibbs, nitric acid is a very stable intermediate kinetic product up to about 523 K (250 °C). Above 573 K (300 °C), HNO_3 decomposes into H_2O and NO_2 .

Aqueous solutions of 40 and 79 mass-% HAN were thermally and catalytically decomposed on Pt/SiO₂ catalysts in a batch reactor, and the results were compared to similar tests performed with 40% HNF solutions [358]. The reactions were tracked by TGA and DTA, and the reaction products withdrawn from a batch reactor were analyzed using mass spectrometry. In the presence of a catalyst, HAN displayed a single exothermic peak, whereas HNF showed two separate exotherms. Catalyst removed from the batch reactor after several injections of HAN showed distinct sintering and crystallite growth of the active metal phase.

The stability of 10%Pt/Al₂O₃/SiO₂ and other catalysts during the catalytic decomposition of 79 mass-% aqueous HAN solutions at 313 K (40 °C) was studied by successive, repeated injections of HAN solution onto the catalyst in a constant-volume batch reactor [359, 360]. The four different catalysts remained active with a fast reaction rate, even in the presence of an excess of residual aqueous solution. Of course, the temperature in the reactor never approached the thousands of degrees a catalyst has to survive in a rocket engine.

Catalysts prepared by drying of xerogels or aerogels in supercritical carbon dioxide may have impressively high surface areas in the freshly prepared state, but once exposed to typical operating temperatures of high-performance HAN-based monopropellants, they will quickly sinter into a solid piece of brick with very little remaining activity, despite having been calcined at 1473 K (1200 °C) for 5 h. Aerogels presented much better thermal stability at high temperature and were more homogeneously dispersed than xerogels. What a catalyst chemist [361] calls “a short ignition delay” (<1 s) is still too long by a factor of 20 for practical rocket applications.

The catalytic decomposition processes of 20, 40, and 79 mass-% HAN and 40 mass-% HNF ([N₂H₅]⁺[C(NO₂)₃][−]) solutions were compared in a constant-volume reactor [362]. The reactions were followed by thermal analysis and by pressure-rise measurement in a constant-volume batch reactor. The 79% HAN solution in contact with a Pt(10%)/Al₂O₃/SiO₂ catalyst showed lower pre-heat temperatures (down to room temperature), higher reaction rates, and more gaseous products than any of the other concentrations, giving the most active system. With the same catalyst, HNF solutions gave lower performances than HAN solutions, suggesting that other catalysts need to be found for this oxidizer.

Spherical granule supports from silica-doped alumina with an average diameter of 1.5 mm were prepared using two procedures starting from the same sol-gel silicon-doped boehmite by dripping it into an oil bath, calcining the solidified droplets at 1473 K (1200 °C), and impregnating them with platinum [363–365]. SiO₂-doped alumina supports (Al₂O₃)_{0.88}–(SiO₂)_{0.12} (Si:Al atomic ratio 6:94) were made using a sol-gel procedure with aluminum tri-sec-butoxide (Al(O–CH(CH₃)–C₂H₅)₃) as precursor and silicon tetraethoxide (Si(O–C₂H₅)₄) to introduce Si as the doping element. The resulting boehmite wet gel was dried under sub-critical conditions (oven, 393 K = 120 °C, 12 h, air flow) to form xerogel samples, which were subsequently calcined at 1473 K (1200 °C). The platinum active phase was impregnated onto the surface of the calcined support through incipient wetness impregnation using an aqueous solution of hexachloroplatinic acid H₂PtCl₆. After drying at 393 K (120 °C), temperature-programmed reduction under H₂ at 673 K (400 °C) led to the formation of medium-sized platinum crystallites (17–21 nm). The catalysts were promoted with 10 mass-% Pt and displayed good efficiency and similar catalytic activity for the decomposition of aqueous 79 mass-% HAN solutions. In a DSC apparatus with a heating rate of 10 K/min, the onset of exotherm of 79% HAN with the most active catalyst (MF) was at 331 K (58 °C). The second most active catalyst (OD) showed

an onset of exotherm at 346 K (73 °C). The bare carriers exothermed only at 363 to 403 K (90 to 130 °C). Similar catalysts were later used for the decomposition of HAN/methanol or HAN/glycerol propellants. Monolithic catalysts studied by the same group were tested with hydrogen peroxide but not with HAN.

Binary aqueous HAN solutions of different concentrations (20, 60, 83 mass-%) were thermally and catalytically decomposed in a constant-volume closed-bomb reactor [221]. The initial reactions of HAN solutions were very similar to those of XM46 propellant. It is easier to test catalysts with HAN solutions in the absence of a fuel, so as not to complicate the reactions. The catalysts were prepared by impregnation of pure or doped supports (alumina, zirconia, barium aluminate, magnesium aluminate, or zirconium aluminate) with monometallic or bimetallic active phases (platinum-group metals [PGM] and non-PGM). Evaluation of the catalysts was carried out using a TGA apparatus and a constant-volume batch microreactor. In the microreactor, 50 μ L monopropellant was added to 100–200 mg of catalyst at room temperature with a micro-syringe through a septum and was then heated at a rate of 4–10 K min⁻¹. The pressure and temperature (catalyst and gas phase) were recorded vs. time. The thermal decomposition started only after the water was quantitatively removed, and the onset temperature was 388 K (115 °C) for the 83% HAN solution using the batch reactor. In the presence of a support alone, a catalytic effect was detected for the alumina and silica-doped alumina by a decrease of the decomposition temperature, due to the acidity of the surface; on the other hand, doping with barium lead inhibited this effect. The presence of an adequate PGM active metal phase led to a further drop of the onset temperature (<313 K = <40 °C). It is encouraging that the decomposition can be triggered at room temperature in the presence of water. The catalytic decomposition was an order of magnitude faster than the thermal decomposition.

In a study of the thermal and the catalytic decomposition of ionic oxidizers in aqueous solution such as HAN, AN, ADN, and HNF, the decomposition was followed by DTA-TGA, constant-volume batch reactor, and dynamic flow reactor coupled with a mass spectrometer [366]. The gaseous products were analyzed by mass spectrometry, whereas the condensed products were analyzed by Raman spectroscopy and acid–base titration in order to establish a balanced equation of the thermal or catalytic decomposition of these oxidizers. A 10% Pt/Al₂O₃/SiO₂ catalyst initially developed for HAN-water decomposition achieved only a low catalytic activity toward ADN-water, HNF-water, and AN-water mixtures. Other monometallic and bimetallic catalysts based on Pt, Fe, Cu, and Zn were prepared and tested to decompose these mixtures.

In addition to HAN/H₂O solutions, the decomposition of HAN/H₂O₂ solutions was also tested on monolithic catalysts. It is reasonable to assume that any catalyst capable of decomposing HAN or high-test peroxide (HTP) will also be capable of initiating decomposition of HAN/H₂O₂ solutions that have been considered as oxidizers for bipropellant or hybrid rocket applications. A batch reactor has been used to study the thermal and catalytic decomposition of binary aqueous HAN and ternary aqueous

HAN/H₂O₂ mixtures [281]. The monolithic catalysts were prepared by impregnation of a coated mullite monolith with monometallic active-phase precursor (Pt or MnO_x) and bimetallic active-phase precursors (Pt+MnO_x). The activity of different catalysts was rated by determining the pressure-rise rate and the reaction products. For a ternary mixture consisting of 31.6 mass-% HAN/31.1% H₂O₂/37.3% H₂O, the relative ranking in the order of decreasing activity at room temperature was MnO_x + Pt > MnO_x > Pt.

Binary HAN aqueous solutions have been decomposed thermally and catalytically [349]. Binary HAN/H₂O mixtures were prepared with different concentrations: 95, 80, and 60 mass-% HAN. The catalysts were prepared by impregnation of alumina/lanthanum oxide with iridium and were characterized by XRD, hydrogen chemisorption, and TEM with a resolution of 3.5 Å. The decomposition processes were followed by DTA, TGA, and processing in a constant-volume batch reactor. In the constant-volume batch reactor, 50 μL of monopropellant was added to 80 mg of catalyst at room temperature under 1 bar of argon flow, using a micro-syringe through a septum, and was then heated at a rate of 10 °C/min. The pressure and temperature were recorded vs. time. This reactor can be used to simulate cold starts or injection by pulses, but not stationary monopropellant flow (steady-state studies). The effect of HAN concentrations on reactivity was studied to determine the best “green” propellant formulations for rocket applications. HAN solutions are more active in the catalytic decomposition in the absence of stabilizers that might poison the catalysts. The (10%)Ir/Al₂O₃/La₂O₃ + 95% HAN reaction showed lower decomposition temperatures, higher reaction rates, and higher amounts of gas-phase products than other mixtures tested.

In a differential scanning calorimeter, a 95% HAN solution started to decompose at 428 K (155 °C) in the absence of a catalyst [367]. When an Ir/Al₂O₃/SiO₂ catalyst was added in powdered form, the exothermic reaction started at 320 K (47 °C). It is not quite clear whether subsequent burning-rate tests were done with a HAN/MeOH monopropellant or simply with 95% HAN/H₂O solutions without an added fuel. Both were called “liquid monopropellant.”

DTA and TGA of aqueous HAN solutions and product gas analysis were conducted for both catalytic and thermal decomposition [368]. These analyses showed that the Ir-based catalyst was effective to reduce the onset temperature of HAN decomposition and that the difference in product gas species was not obvious between catalytic and thermal decompositions. The reaction mechanism of catalytic decomposition was almost the same as that of thermal decomposition. Nitric acid was generated at a lower temperature in catalytic decomposition than in thermal decomposition. The Ir-based catalyst could not change the reaction mechanism but could activate the reaction path of HNO₃ generation.

Dynamic HAN Decomposition Reactors

A dynamic reactor with mass spectroscopy online product analysis was used to study the thermal and catalytically accelerated decomposition of HAN and HAN-based monopropellants [364, 369]. The activity of different catalysts was evaluated by

determining the type and rate of evolution of reaction products (N_2 , O_2 , N_2O , NO , and NO_2). The analysis results were supplemented by Raman spectroscopy of the aqueous condensates collected from the reaction products in a cold trap prior to admitting the non-condensable gases into the mass spectrometer. The thermal and catalytic decomposition of 80 mass-% HAN gave large amounts of N_2 , lesser amounts of NO , and traces of N_2O and NO_2 . A powdered and a granular, spherical catalyst with 10% Pt were tested [370]. The isothermal tests at 323 K (50 °C) gave the best activity, with a powdered catalyst resulting in complete decomposition of the HAN solution. Coarser, sphere-shaped catalysts gave only incomplete HAN decomposition due to channeling of part of the liquid through the catalyst bed. Likewise, the thermal (non-catalytic) decomposition over an inert carrier at 473 K (200 °C) gave only a partial decomposition reaction.

Two parallel reactions were proposed based on the reaction product analysis [363]:

In establishing a model of the HAN decomposition process, 11 reactions were identified as participating in the condensed-phase decomposition reactions of HAN, starting with a proton transfer. The ratio of $\text{N}_2\text{O}/\text{NO}$ generated during HAN decomposition depended on the catalytic surface and temperature. The observed increase in $\text{N}_2\text{O}/\text{NO}$ ratio with Shell 405 catalyst suggest multiple surface-sensitive reaction pathways involving HNO , HNO_2 , and hyponitrous acid $\text{H}_2\text{N}_2\text{O}_2$. It was recommended to study the effects of the SHAN stabilizers in the liquid propellants to determine their roles in the reaction mechanism because they may act as inhibitors and catalyst poisons.

Chinese catalysts intended for the decomposition of HAN-based monopropellants were prepared by incipient wetness impregnation of six different active metals on Al_2O_3 (20–40 mesh; BET surface area 204 m^2/g) or SiO_2 (20–40 mesh; BET surface area 477 m^2/g) with an aqueous solution of the corresponding metal precursors to give an active metal content of 5 mass-% [371]. The catalysts were dried at 353 K (80 °C) for 12h and then calcined at 573 K (300 °C) under N_2 for 5h. Prior to the catalytic tests, the catalyst were *in situ* reduced with H_2 at 623 K (350 °C) for 2h. Two kinds of HAN-based propellants were used to test the catalysts: HAN80 and HANGLY26. The former is a binary mixture containing only 80 mass-% HAN in water and no fuel, and the latter is a ternary mixture composed of 60% HAN, 14% glycine, and 26% water. The catalytic activity was evaluated by three methods: an open-cup (“spot plate”) experiment for rapid screening of catalysts; a thermal analysis method for determining the onset temperature of decomposition; and an isothermal, isochoric batch reactor method for simulating pulse-mode operation in a real thruster with 20 pulses in short sequence. Catalyst temperature and chamber pressure were recorded during each 20-pulse sequence. An 8-mg sample of the catalyst was put into a quartz crucible of the DTA appa-

ratus (Shimadzu DT-20B), and then 30 μL of the 80% HAN solution was added to the catalyst below room temperature by using ice cooling. The catalyst was not spontaneous at room temperature. The crucible was then heated at $10\text{ }^{\circ}\text{C min}^{-1}$ under a purge of N_2 gas, and the first sign of an exotherm was recorded. All the catalysts listed in Table 28 lowered the ignition temperature of 80% HAN to some extent. Both Os and Ir supported on SiO_2 exhibited the best catalytic activities, with the ignition temperatures of 307 K ($34\text{ }^{\circ}\text{C}$) and 294 K ($21\text{ }^{\circ}\text{C}$), respectively. Other supported metal catalysts, such as Pt, Ru, Rh, and Pd, had poor activities, with an ignition temperature of above 343 K ($70\text{ }^{\circ}\text{C}$). This is in contrast to the results obtained by Kappenstein et al., who reported that supported Pt was the most active catalyst.

Table 28: Ignition temperature of 80 mass-% HAN solution on various supported metal catalysts.

	Ignition temperature, $^{\circ}\text{C}$							
	Metal		Ru	Rh	Pd	Os	Ir	Pt
	None	None						
Support								
SiO_2	74	—	69	84	98	34	21	90
Al_2O_3	—	78	78	83	100	—	77	82

Data source: [371]

Some catalysts were soaked in 69% nitric acid prior to the tests and dried, which greatly enhanced their activity to the point that HAN/glycine propellant could be ignited at room temperature.

In tests of 80% HAN decomposition with Ir/ Al_2O_3 and Ir/ SiO_2 catalysts at room temperature, the Ir/ SiO_2 catalysts were more active [372].

3.4.4 Analytical Methods for Hydroxylammonium Nitrate Solutions

The analytical methods described here apply only to oxidizer solutions and not to formulated HAN-based monopropellants containing fuels. Analytical methods for HAN-based monopropellants are described in *Encyclopedia of Monopropellants*, chapter “Hydroxylammonium Nitrate-Based Monopropellants.” See also [373, 374].

A survey of 61 references from the literature resulted in a review of the quantitative methods most widely used to determine hydroxylamine and its salts, including volumetric, electrochemical, and spectrophotometric methods [375].

3.4.4.1 Volumetric Methods

Acidimetric Methods

Because of the different pKs of nitric acid and hydroxylammonium ion, the two can be determined by acidimetric titrations with recording of the pH, typically done in an autotitrator [376].

The free nitric acid content in HAN solutions and in HAN-based monopropellants can be determined by autotitration with electrometric end-point indication. For small acid contents ($<0.5\%$ HNO_3), a known amount of HNO_3 is added before the titration, and the difference is calculated after the titration [377].

Redox Titration Methods

If standardized triphenylphosphonium permanganate solutions are used for titration of hydroxylamine or its salts in pyrophosphate buffers, and if a water-immiscible organic solvent is layered below the water, the end point can be detected by the appearance of a purple color in the organic phase [378].

3.4.4.2 Gas Chromatographic Methods

Hydroxylamine can be derivatized with acetone to form the ketoxime, which is volatile, and can be detected in trace quantities in a gas chromatograph with a flame ionization detector [379].

3.4.4.3 Liquid Chromatographic Methods

Reaction products of HA and HAN decomposition were analyzed using HPLC and ion chromatography using a Dionex P680 system with a Dionex 1024 dio-array detector equipped with an Acclaim C18 5- μm , 120- $\text{\AA}$, 4.6 $\times$ 250 mm column with a 95:5 water:acetonitrile isocratic mobile phase [98]. The method also served to measure the concentration of undecomposed HAN as a function of time. The UV absorption of the HPLC effluents was measured at 201 and 254 nm.

Mixtures of hydroxylamine, *N*-methylhydroxylamine, and *N,N*-dimethylhydroxylamine and their salts can be analyzed by ion chromatography [380].

3.4.4.4 Infrared Spectroscopic Methods

Infrared spectroscopy is an ideal method for the analysis of HAN and HAN contaminants in the solid state or in aqueous solutions [381].

3.4.4.5 UV-Visible Spectroscopic Methods

The total nitrate concentration in HAN and HAN-based monopropellants can be determined by measuring the absorption at 205 nm. This method is useful when monitoring the HAN concentration during the preparation of concentrated HAN solutions from diluted HAN solutions by evaporation of water [382]. It is also useful when monitoring the electrolyte withdrawn from diaphragm HAN production cells [383].

3.4.4.6 Mass Spectrometric Methods

The analysis of HAN for metal ions at the level of 1–10 ppb is possible using inductively coupled plasma-mass spectrometry (ICP-MS) [384]. Sensitivity levels using a Perkin-Elmer model 500 ICP mass spectrometer and appropriate internal standards were approximately 1 ppb. From one prepared and diluted sample, HAN solutions were an-

alyzed for 19 elements, including sodium, magnesium, aluminum, calcium, strontium, barium, vanadium, niobium, chromium, and molybdenum. The analysis was repeated five times per sample and required approximately 3 min for the total analysis. The method can be expanded to include other metals, with the introduction of a set of standards for new analytes. This technique is applicable not only to a finished product but also to all starting reactants and production-process intermediate streams and propellants.

3.5 Ignition of Hydroxylammonium Nitrate Solutions

The same methods that have been tested for the ignition of XM46 were also tried for the ignition of HAN solutions in the absence of fuels, including catalytic, electric, and laser ignition. The ignition of HAN solutions in the absence of fuels is a less energetic reaction. Sometimes HAN solutions ignited by accident rather than on purpose. Because the major part of liquid burn propellants and liquid monopropellants consists of HAN, it is interesting to study the ignition behavior of HAN solutions by themselves in the absence of fuels.

A CO₂ laser was used to initiate and sustain combustion of HAN and TEAN at pressures of 1 and 4 atm and heat fluxes of 100 and 400 W/cm² [385]. A triple quadrupole mass spectrometer and micro-thermocouples were applied for measurements of temporal species evolution and temperature profiles. Flame behavior was observed using a high-magnification, high-speed video system. At 400 W/cm², the sequence of flame and species evolution was the same for each material at the two pressure conditions; however, mol fractions of some major species measured were different. In tests at different pressures, the ignition delay of HAN increased with increasing pressure, while the ignition delay of TEAN and XM46 decreased. Additional measurements of species and temperature were made for liquid HAN solution and XM46 droplets to obtain the condensed-phase temperature and species evolution during laser-assisted pyrolysis. Droplets with diameters of 500–800 μm were suspended from type K thermocouples in argon at sea-level pressure and were heated by a CO₂ laser at 50 W/cm². For HAN, the temperature of the droplet experienced two plateaus at ~440 K and ~540 K during the evaporation of H₂O and the decomposition of HAN, respectively. Although no visible flame was observed during the HAN pyrolysis, a brown gas evolved, and the surface of the droplet pulsed. During the HAN decomposition, evolution of NO₂, N₂O, NO, N₂, and H₂O was consistently measured, with HONO only at very small amounts and no O₂ or HNO₃ detected.

In addition to thermally or catalytically induced decomposition of the HAN-based propellants, HAN decomposition by electrolysis has been suggested as a viable alternative for applications in micro-scale thrusters, since thermal management for HAN decomposition would be very difficult to control in small propulsion devices. The other potential benefits of electrolytically induced decomposition of HAN-based

liquid propellants would be low ignition temperature, reduced power requirement, enhanced system durability and reliability, and reduced cost. Extensive studies on electric and electrolytic ignition of XM46 propellant is described in *Encyclopedia of Monopropellants*. Investigators wanted to avoid interference by the fuel component in HAN-based monopropellants, and therefore examined the electrolytic ignition of HAN solutions without fuels.

Electric-current-stimulated ignition of aqueous HAN solutions has been studied experimentally, and electrochemical mechanisms pertaining to HAN-water solutions were established and incorporated into an existing chemical kinetics scheme [261]. The ignition process was treated numerically using a constant-pressure, homogeneous reactor model. Prototype micro-fin electrodes consisting of a Teflon screen sandwiched between two stainless steel meshes and attached to a power supply were reexamined to verify the electrolytic ignition concept. Experiments were conducted using these electrodes, and it was found that the solutions can be ignited at elevated pressure. Based on the temperature-rise profile and the evolution of condensed and gas-phase species, the effects of electric current, voltage, volume, initial temperature, and HAN concentration on the ignition delay were determined and fitted into a kinetic model. A set of ten electrochemical and chemical liquid-phase reactions was included in the analysis, involving 12 species, namely HAN, NH_2OH , HNO_3 , HONO , HNO , N_2O , N_2 , NO , NO_2 , H_2O , H_2 , and O_2 . Among them, H_2 and O_2 appear only in the gas phase. While ignition starts in the liquid phase, combustion occurs in the gas phase and was also modeled using CHEMKIN. The gaseous species produced by the condensed-phase reactions subsequently participate in a series of gas-phase reactions, many of them exothermic. A total of 32 species and 151 reactions in gas phase were considered in the gas-phase model. Results indicated that the electric current significantly enhanced HAN decomposition compared with the pure thermal decomposition process. At a constant temperature and a specified initial volume, increasing the total current decreased the ignition time delay of HAN-water solutions (Figure 43).

In similar tests, the ignition of HAN solutions (no fuel added) was examined [292]. The purpose of that study was to identify the various parameters and mechanisms affecting the electrolytic ignition of HAN-based monopropellants. Electrochemical mechanisms were established and incorporated into an existing chemical kinetics scheme. The ignition of HAN-water solution by electrolysis was treated numerically using a constant-pressure, homogeneous reactor model. A stiff ordinary differential equation solver was used in the analysis to handle the highly stiff species conservation and the energy equations. The analysis focused on the temporal evolution and spatial distribution of temperature and condensed and gas-phase species. Parametric studies were conducted to investigate the effect of electric current, voltage, volume, initial temperature, and HAN concentration on the ignition time delay. The ignition time delay was found to decrease with increase in current, temperature, and HAN concentration and to increase with volume.

Figure 43: Ignition time delay vs. current at an initial temperature of 300 K and 1 atm pressure. (Reproduced and modified from [261].)

In a study of the thermal and electrolytic decomposition and ignition of aqueous solutions of HAN, experiments were conducted to demonstrate the feasibility of electrolytic ignition of HAN-based monopropellants [386]. Electrolysis of HAN solutions leads to formation of NH_2OH , HNO_3 , HONO , HNO , N_2O , N_2 , NO , NO_2 , H_2O , $\text{H}_2(\text{G})$, and $\text{O}_2(\text{G})$. These species then initiate a series of gas-phase reactions, governed by the H-O-N kinetics scheme, that lead to ignition. Electrochemical mechanisms were incorporated into an existing chemical kinetics scheme for thermal decomposition of HAN/water solutions. The analytical model treated the liquid and gas phases separately and matched their respective processes at the interfacial boundary to determine the overall decomposition and ignition characteristics. Model predictions were compared to experimental data for species evolution in the condensed phase, as well as to laser-induced ignition delay of 13-M HAN/water solutions. The effects of electric current (0–2.5 A), propellant volume (0.1–0.3 mL), initial temperature (300–450 K), and HAN concentration (9–13 M) on the ignition behaviors were investigated systematically. The ignition delay decreased with increasing electric current as a power-law function

$$t_{\text{ign}} = A \times I^{-n}$$

where $A = 3.95$ and $n = 0.95$ for a 0.1-mL 13-M HAN/water solution at an initial condition of 300 K and 1 atm. The exponent n and coefficient A were decreasing functions of the initial temperature. A titanium micro-fin electrode module was used that consisted of

eight evenly spaced parallel fins with dimensions of $9 \times 19 \times 0.25$ mm, separated from each other by 1 mm. The electrode surface area ranged from 1050 to 4200 mm², and the input voltage ranged from 7 to 26 V, similar to conditions described by Risha et al. [387]. Rates of gasification of 15-mL samples of XM46 were measured as a function of electric voltage, current, and electrode geometry. Peak reactivity was achieved after ~0.75 s. Reaction rates and activation energies for eight reaction steps were entered into a kinetic model to derive a global decomposition rate for HAN by itself in aqueous solutions. The electrolytic ignition results were then compared to laser ignition of 13-M HAN by a laser energy flux of 400 W/cm² (120 W into a test sample of 0.3 mL solution with a height of 10 mm). See also [293, 388].

The electrolytic ignition and decomposition of various HAN ternary stoichiometric mixtures prepared according to zero oxygen balance to carbon dioxide showed multiple stages of decomposition depending on the type of fuels added into the HAN solution [389]. While concentrated HAN solution (73 mass-% HAN) had only a single stage of decomposition, the saccharides-based HAN ternary mixtures had three stages of reaction with increased energy release. Based on calorimetric measurements, there was a linear relationship between the electrical resistivity of HAN ternary mixtures and reaction rates in the first stage of reaction, indicating the presence of Joule heating in the process. The influence of electrical resistivity of ternary mixtures became negligible in the second stage of reaction. The release of combined electrical and thermal energy is important in the first-stage decomposition of HAN ternary mixtures.

In a study of the electrolytic decomposition of HAN/water solutions using graphite electrodes, it was noted that the decomposition reaction proceeded in two stages [390]. Electrical energy was consumed for 5 s before the stage-1 reaction ceased. An interesting phenomenon was observed in the stage-2 reaction, in which the decomposition of HAN resumed after the power supply was switched off. A series of spectroscopy and microscopy analyses confirmed that the production of nitric oxide (NO) in the stage-1 reaction caused the formation of nitrous acid (HNO₂), which led to a further autocatalytic reaction. Several reaction mechanisms were proposed and compared with the case of using copper electrodes. Graphite electrodes were identified as more energy efficient in initiating the electrolytic decomposition of HAN/water solution, as lower energy consumption (342 J) was achieved in comparison to the energy required to achieve ignition with copper electrodes (1926 J).

Decreasing the initial volume of the HAN solution also expedited the electrolytic ignition process, indicating that the electrolytically induced HAN ignition should be suitable for applications in small thrusters. It was also seen that at a constant volume and temperature, a more concentrated solution of HAN ignited faster than a less concentrated solution if equal electric current was applied. The same apparatus was later used to study the ignition of XM46 [387].

Hydroxylammonium nitrate solutions as liquid oxidizer for hybrid rockets are easy to handle because they are not toxic, have a low vapor pressure, and are stable at ordinary temperatures and pressures. In studying the decomposition of HAN solution

droplets in a hybrid rocket engine, it was important to observe a single droplet because atomized HAN liquid oxidizer consists of many droplets. HAN concentration affects the ignition characteristics of the HAN droplets. The relationship between HAN concentration and ignition characteristics of the HAN droplets was studied by obtaining the decomposition delay time of the HAN droplets [391].

The electrolytic decomposition of ADN-HAN mixtures in a polymer micropropulsion system was studied as an ignition method for monopropellant or hybrid micro-rockets [392].

3.6 Strand Burning of Solid Hydroxylammonium Nitrate Pellets and Hydroxylammonium Nitrate Solutions

Strand-burning data have been obtained for the burning of HAN by itself as a solid as well as in aqueous solutions in the absence of any combustibles. Nobody was planning on using HAN by itself as a propellant, but since the burning rates of HAN-based monopropellants are determined mostly by the rate of the decomposition of HAN the precedes the combustion, this was important information to have. Also, the major ingredient in all HAN-based monopropellants is HAN itself, usually in concentrations around 60 mass-%, so its decomposition influences the burning rates more than any of the other ingredients do.

It is nearly impossible to obtain solid HAN at room temperature. Therefore, most of the experiments have been done with HAN solutions instead of with the pure compound.

In a study at Sandia National Labs in Albuquerque, New Mexico, HAN solutions and HAN-based propellants were burned in a back-lit strand burner inside a windowed pressure vessel at pressures up to 34 MPa (5000 psi) [237, 393–395]. High-speed cine shadowgraphy was used to capture the decomposition phenomenon. The sample-holder capillary tubes were 5.2–9.1 mm in internal diameter, and the samples were 40 mm long. Later samples were burned in a rectangular cell that was 1.8×1 mm wide. The imaging system was capable of operating at a framing rate of 60 frames/s. Ignition was achieved by an electric discharge. In looking at the burning-rate results, it was noted that there is a decrease in the average volumetric turbulent burning rate of HAN solutions as well as XM46 when the pressure is increased from 6.7 to 34 MPa (1000 to 5000 psi). This “negative pressure exponent” was at first unexplained, but it was later attributed to changes in the stability of the liquid–gas interface with pressure. At the lower pressure, there are more interfacial instabilities, and small droplets get thrown out of the burning meniscus into the flame front. At low pressure, the apparent decomposition rate was approximately proportional to $1/P$ due to hydrodynamic instabilities, which become less noticeable at higher pressures. A “density ratio” parameter was introduced to obtain better correlation of the results. Low-density ratios are associated with

meniscus decomposition fronts, and high-density ratios give flatter flame fronts. At higher pressure, the apparent decomposition rate was proportional to the HAN concentration. The lowest concentration at which HAN decomposition could be sustained was between 3 and 5-M HAN. Water that formed during the decomposition of 5 to 9-M solutions was mostly in the liquid phase (wet steam). The solution concentration has to be at least 11 to 13-M to obtain dry steam. The experimental results confirmed the strong positive influence of the effective diameter of the tube and the negative influence of pressure on the burning rate of water solutions of HAN. It was found that 3.12-M HAN could not sustain decomposition, even when initiated with an electric discharge of as much as 10 J. For solutions of 5.20, 7.02, and 9.10-M HAN, the mass decomposition rate first decreased until reaching about 13 MPa, and then it became independent of pressure. The abnormal behavior of burning rates at $p < 13$ MPa was explained by introducing an “apparent mass decomposition rate.” At low pressures, the interface has a large meniscus with small corrugations. A larger meniscus corresponds to a larger decomposition area and hence a larger apparent mass decomposition rate. As the pressure was increased, the meniscus became less pronounced, becoming indiscernible at pressures above 13 MPa, and at that point the apparent decomposition rate decreased. The apparent decomposition rate for 11.05 and 13-M HAN solutions showed a different trend because it decreased monotonically with pressure. The unusual apparent burning-rate dependence on pressure is the result of a pressure-independent burning rate and hydrodynamic instabilities, which play a lesser role at higher pressures (smaller bubbles).

Combustion studies were conducted on solid crystalline HAN and its water solutions in a constant-pressure bomb within a pressure range of 0.1 to 36 MPa with sample diameters of 7 mm [396]. The test results indicated that solid crystalline HAN was not capable of self-sustained burning at atmospheric pressure. When ignited using a hot Nichrome wire, a slow layer-by-layer decomposition (“fizzing”) was followed by an abundant foam evolution. Above 0.3 MPa the decomposition was found to be self-sustaining, but the velocity was unusually low, only about 50 $\mu\text{m/s}$. The burning-rate equation (Robert de Vieille’s law) of a pellet of burning solid HAN (density 1.78 g/cm^3) had an abnormally high pressure exponent, similar to that of a 9-M HAN solution. For pressures below 10 MPa, the pressure exponent was 1.5 to 2.6 (Figure 44).

It was also found that in contrast to aqueous solutions of HAN and HAN-based liquid propellants, the burning rate of the solid substance increased in a controlled fashion up to 20 MPa, after which it increased even more rapidly with pressure. For pressures >20 MPa, the transitions from slow to extremely fast burning were observed immediately after ignition, and burning rates could not be measured. The pressure exponent was 1.6 up to 1.1 MPa, became as high as 2.6 at $1.1 < p < 2.1$ MPa, and decreased to 1.5 between 2.1 and 2.3 MPa. HAN solutions burning in the turbulent regime showed a sharp decrease in the pressure exponent once the pressure exceeded 10 MPa. In some instances, the burning rate of HAN solutions even decreased with increasing pressure. Solid HAN combustion in the 1.5-L windowed pressure chamber was non-luminescent,

Figure 44: Strand burning rate of solid HAN. (Republished and modified from [396], with permission of Springer Nature BV © 2000; permission conveyed through Copyright Clearance Center Inc.)

such that the high-speed slit camera had to use backlighting or front illumination. When the logarithm of the burning rate of solid HAN vs. $1/T$ was plotted, straight lines with three slightly different slopes were obtained, depending on the pressure regime (<1.1 , 1.1 – 2.1 , and 2.1 – 20 MPa).

Although the main objective of the following work was to optimize burning rates of HAN solutions with methanol and AN, one initial series of strand burning-rate tests was conducted with HAN solutions of five different concentrations from 50 to 95 mass-% HAN without addition of any fuels [397]. The measurement of linear burning rates was done in glass tubes, and the progression of the flame front was recorded with a medium-speed video camera. Burning rates were measured as function of HAN concentration and pressure. As shown in Figure 45, the burning rate peaked at 80 mass-% HAN. The burning rate of 80-% HAN solutions was not very dependent on pressure.

Surprisingly, the burning rates of 85 and 95% solutions were less than that of the 80% solution. The burning rate of a 95 mass-% solution was similar to that of HAN crystals. Figure 46 is a comparison of the solution burning-rate data with data on HAN crystals obtained by Kondrikov et al. [396], also in comparison to solution data obtained by Matsuda [397].

Note: Kondrikov in Figure 46 is Kondrikov et al. [396]

The combustion modes of 64 and 50 mass-% solutions were the same as that of the 80 mass-% solution. Solutions containing 85 and 80 mass-% HAN had two burning modes: a mixed mode and a high-burning-rate mode. This may indicate that HAN concentration changes the structure of the combustion wave, and the structure character governs the burning rate. The Matsuda et al. [397] work is remarkable for the high-quality color images taken of the HAN decomposition flame front. This vividly illustrates the decomposition at the interface between the liquid and the combustion zone.

Seven aqueous solutions with 95, 85, 82.5, 80, 77.5, 64, and 50 mass-% HAN were prepared in order to measure the effects of HAN concentration on burning rate [398]. For HAN solutions, 95 mass-% HAN is the maximum concentration that can be prepared at room temperature. The sample solutions were placed in glass tubes and burned in a strand burner purged with nitrogen gas at 1–10 MPa. The initial temperature of the sample solutions was set at 297 K (24 °C). The combustion wave of HAN aqueous solutions in the glass tubes was observed with a medium-speed video camera at 500 frames per second. The linear burning rate had a peak at approximately 80 mass-% HAN in water. It is very strange that in the range 80–95% HAN, the burning rate decreased with increasing HAN concentration, and the curvature of the burning rate vs. pressure curve changed from convex to concave (Figure 47).

Figure 47: Linear strand burning rates of 80–95% HAN solutions. (Republished and modified from [398], with permission of © 2010 American Institute of Aeronautics and Astronautics; permission conveyed through Copyright Clearance Center Inc.)

This phenomenon has been explained as a hydrodynamic instability in which droplets of liquid are ejected into the flame zone. The burning rate of a 95% solution was very similar to that of an anhydrous HAN crystal. The burning rates of 50–80% solutions increased with increasing HAN concentration, and the curvature of the lines in the $r_b = f(p)$ graph remained the same. The burning rate of a 95 HAN/5 AN/8 H₂O oxidizer solution increased abruptly at 3.5 MPa. A monopropellant of 100 parts of this oxidizer with 8 parts methanol showed a similar behavior at the same pressure, but a monopropellant of this oxidizer with 21 parts methanol had a steady and linear burn rate curve, as one would want to have for a well-behaved monopropellant.

The combustion characteristics of HAN aqueous solutions in the absence of fuels were studied, and it was found that the role of the two-phase region is very important and that the intense boiling of water by superheating and bursting of bubbles is responsible for the high burning rate [399]. The evaluated bubble nucleation rate coincided with burning rate at very high pressure. Hydrodynamic instabilities accelerate the burning rate. The pressure dependency of hydrodynamic instabilities was estimated, and it supported the observed phenomena. It was found that the instability was strongly affected by the Markstein number.

Additional burning-rate results are summarized in *Encyclopedia of Monopropellants* for HAN-based monopropellants in which HAN is not decomposed by itself but in combination with various water-soluble fuels.

It seems that many less-energetic hydroxylammonium salts (less energetic than HAN), although they have negative enthalpies of formation, are also capable of burning in a strand burner. That includes hydroxylammonium chloride and hydroxylammonium sulfate, which are not suitable as rocket propellants, but they have been examined for their safety properties [400]. The critical diameter and the linear burning rate of solid hydrazinium and hydroxylammonium chloride and sulfate were determined in 36-, 39-, and 45-mm-diameter tubes at atmospheric pressure. Hydroxylammonium chloride burned stably at 0.1 mm/s in 44-mm tubes but was quenched in 40-mm tubes. Addition of Cu₂Cl₂ increased the burning rate to 0.25 mm/s. Hydroxylammonium sulfate burned in all three tube diameters at rates of 0.16, 0.10, and 0.07 mm/s in tubes with diameters of 45, 39, and 36 mm, respectively. See also [401].

OXSOL is a name for oxidizer solutions containing HAN and other oxidizers (e.g., 70 mass-% HAN, 15% AN, and 15% H₂O). The strand burning rates of OXSOL-2 were measured in transparent test tubes in a windowed liquid-propellant strand burner [402–404]. The burn rate of OXSOL was deduced from the regression history of the liquid surface as seen in film recordings of the event. The burn rate was found to be a function of test tube diameter and ranged from 40 to 550 mm/s for the pressure range of 2.5–20 MPa. The tests were conducted in tubes with three different diameters. In all diameters, OXSOL exhibited two slope breaks, with a pressure exponent of 2.87 from

2.5 to 5 MPa, 0.42 from 5 to 9 MPa, and -0.78 above 9 MPa (see Figure 48). The burning rate in the low-pressure region below 5 MPa can be expressed by the equation

$$r_b = ap^{2.87}$$

with

$$a = 3.69\exp[0.07(D - 8.3)].$$

where r_b is the burning rate in mm/s, p is the pressure in MPa, and D is the tube diameter in mm. The burning rate in the medium-pressure region from 5 to 9 MPa can be expressed by the equation

$$r_b = ap^{0.41}$$

with

$$a = 184\exp[0.06(D - 8.3)]$$

The burning rate in the high-pressure region above 9 MPa can be expressed by the equation

$$r_b = ap^{-0.78}$$

with

$$a = 2416\exp[0.04(D - 8.3)]$$

The format of burning-rate data representation in Figure 48 is exemplary, and we wish that all burning-rate data by other investigators and in other publications would be

Figure 48: Burning rate of OXSOL-2 as a function of pressure. (Reproduced and modified from [404].)

presented in this format. Some other publications don't even state the strand diameter used. The dependence of the burning rate on strand diameter is clearly evident, although the cutoff pressure below which no further propagation takes place is not clearly marked. The effect of tube diameter on the burning rate of OXSOL is due to hydrodynamic instability of the burning surface, based on the simulation of surface ripples with a vibrating membrane model. The burning-rate slope break at 5 MPa was found to be very close to the slope break at 5.5 MPa in the plot of the ratio of heat of vaporization to the boiling point of water vs. pressure. This implies the involvement of the water-vaporization process in the low-pressure combustion of OXSOL.

The linear burning rates of aqueous HAN solutions and solutions containing methanol and nanoscale fumed silica were observed in a strand burner at pressures between 3 and 22 MPa in a constant volume bomb with pressure (non-optical) measurement [405, 406].

The addition of activated charcoal to HAN solutions lowers the onset temperature of thermal decomposition and increases the burning rate. The large surface area of activated carbon initially acts as a catalyst, but at later stages of the reaction, the carbon is consumed as a fuel and burned to carbon dioxide. The following several references are discussed here for their dealing with the catalytic activity of activated carbon and are also discussed in *Encyclopedia of Monopropellants*, where the addition of active carbon to concentrated HAN solutions provides a recipe for a monopropellant.

The combustion 95 mass-% HAN/water solutions in the presence of highly specific surface-area-activated carbons was investigated in a constant-pressure bomb within the pressure range of 1–6 MPa [407, 408]. The linear burning rates increased for the HAN solution mixed with activated carbons compared to those of HAN solution by itself. The thermal decomposition of 95 mass-% HAN/water solutions spiked with activated carbons was measured using DTA-TGA. The addition of activated carbon decreased the onset of decomposition temperature from 458 to 359 K (185 to 86 °C). The volatile products formed in the course of thermal decomposition of HAN spiked with activated carbons were characterized by electron ionization mass spectrometry analysis. Primary products of HAN decomposition were at $m/z = 33$ (NH_2OH) and $m/z = 63$ (HNO_3), which decomposed to form secondary products such as N_2O , NO , HNO_2 , NO_2 , and O_2 . The concentration of NO_x emissions during thermal decomposition of 95 mass-% HAN/water solutions was reduced by ~30% in the presence of activated carbons.

The burning rate of HAN doped with activated carbon increased to 400 mm/s at a combustion bomb pressure of 6 MPa [409].

The increase in burning rate as the result of using different carbons with different BET surface areas and porosities was most pronounced at 6 MPa and was barely noticeable at 1 MPa [410]. The burning rate as a function of the amount of carbon added increased almost linearly with the carbon concentration (at 4 MPa bomb pressure), from 100 to 210 mm/s at 5 vol-% carbon.

In *Encyclopedia of Monopropellants*, the chapter “Hydroxylammonium Nitrate-Based Monopropellants” contains a much more detailed summary of strand burning rate experiments of HAN solutions with various fuels and burning-rate catalysts added.

3.7 Thermal Stability of Hydroxylammonium Nitrate Solutions

Because HAN is rarely stored in the solid state, the summary provided here deals only with the thermal and storage stability of HAN solutions. This is the section on thermal stability as opposed to storage stability. The two properties are closely related to each other, and it is difficult to divide this subject. The section on storage stability follows later. Until 1992, HAN solutions were available only as 24% solutions, and a shipping classification for this material was in place for a long time. The shipping permit for more concentrated 81% solutions was obtained only in 1993.

Prediction of thermal stability requires the knowledge of both the thermodynamics and the kinetics for the given system.

During the investigation following an accident with HAN solutions at Hanford, Washington [411], the thermal stability of 24 mass-% HAN was tested in the Reactive System Screening Tool (RSST) [263, 412]. The RSST is a calorimeter equipped with temperature and pressure probes as well as a heater that can heat a liquid sample at a preprogrammed rate; it is used for rapid measurement of reaction thermal behavior at temperatures up to 673 K (400 °C) and pressures up to 3.44 MPa (500 psig). A 10-mL sample cell typically made of glass or quartz is placed inside a pressure vessel (400 mL) that can withstand pressures up to 3.44 MPa (500 psig). The RSST can be used not only for screening the reactive chemicals but also for designing emergency-relief devices. A fixed heating rate of 1 °C/min was used for temperatures up to 673 K (400 °C). The shutdown pressure limit was 3.1 MPa (450 psig). Initial nitrogen-pad pressures of 1.72 MPa (250 psig) were used to reduce material loss (water evaporation) from the sample cell. Once the temperature in the sample reached 453 K (180 °C), the pressure and sample temperature increased dramatically. Quite often, the glass sample cells were broken into pieces due to the violence of the reaction.

Thermal stability tests were conducted with a nitric acid/HAN/potassium fluoride solution typically used for plutonium dissolution in nuclear reactor fuel element reprocessing [413]. Tests were carried out in the RSST. In most cases, the calorimeter was pressurized with nitrogen to reduce evaporation of the liquid sample during heating. For the HNO₃/HAN/KF solution, an autocatalytic exothermic reaction occurred between 386 and 404 K (113 and 131 °C) with 2.06 or 0.34 MPa (300 or 50 psig) nitrogen inside the RSST vapor space. At ambient pressure, the solution boiled at about 383 K (110 °C). After extensive boiling, the concentrations of HNO₃ and HAN increased, and the autocatalytic reaction occurred suddenly. Tests were also conducted with 1000 ppm Fe as a contaminant present in the solution. The Fe

addition reduced the range of the autocatalytic reaction initiation temperature to 378–393.5 K (105–120.5 °C). With iron at ambient pressure, the autocatalytic reaction occurred at 381–382 K (108–109 °C). Under actual Purex operating conditions, the dissolving temperature is more like 323–333 K (50–60 °C). Increasing the nitric acid concentration to 3M decreased the reaction initiation temperature to 375–376 K (102–103 °C). Increasing the HAN concentration increased the exothermic temperature rise ΔT of the reaction from 10–30 °C to greater than 40 °C. Increasing both reactants to 3M nitric acid and 0.9M-HAN yielded a reaction initiation temperature of 364 K (91 °C) (with or without iron), the lowest observed in this study.

Another method used to study decomposition of HAN solutions involved an automatic pressure-tracking adiabatic calorimeter (APTAC), [414] which is similar to an accelerating rate calorimeter (ARC). This instrument provided more accurate data than the RSST or ARC. Adiabatic calorimetry is an extremely useful tool to assess thermal hazards of reactive chemicals. It can minimize heat losses by keeping the temperature of the sample surroundings close to the temperature of the sample. The APTAC can be operated in a variety of test modes, such as heat-wait-search heat ramp, and isothermal aging, with temperatures up to 500 °C and pressures ranging from vacuum to 13.76 MPa (2000 psia), and it can track exotherms at heat-rise rates from 0.04 to 400°/min.

The APTAC can use a pressure-compensating technique in which the pressure outside the sample cell is controlled to match the pressure inside the sample cell. This allows use of a thin-wall sample cell that, when combined with the usual charge volume, can produce low thermal inertia data. For the 24% HAN examination, the measurements were conducted in glass sample cells of nominal 100-mL volume, which provided a metal-free environment for the reactions, and also in titanium and stainless steel sample cells of nominal 130 and 50-mL volumes, respectively, to test the effect of metals on the thermal decomposition of HAN.

Teflon-coated thermocouples were used to prevent the contact of HAN solution with the metal thermocouple sheath. The APTAC cannot measure heat of reaction directly, but the system consisting of sample and sample cell was kept nearly adiabatic during runaway reactions. Part of the heat of reaction was absorbed by the sample cell, and the remainder was used to increase the temperature of the sample and vaporize volatile materials.

Two operating modes were used with the APTAC: a heat-wait-search (HWS) mode and a heat-soak-search (HSS) mode. In the HWS mode, the sample was heated at 2°C/min to a selected starting temperature, and the temperature was allowed to stabilize for 25 min, following which the APTAC searched for exothermic behavior. During the search period, the temperature of the containment vessel gas was adjusted to match that of the sample. If the self-heating rate of the sample was greater than a preset threshold (0.05 °C/min), the apparatus tracked the reaction adiabatically until the reaction ended or one of the shutdown criteria was met. If no exotherm was detected, the apparatus heated the sample to the next step-up search temperature,

and the steps repeated until one of the shutdown criteria was met. The onset temperature was defined as the temperature at which an exotherm is detected, and it is usually the lowest temperature at which the sample self-heating rate surpasses the preset threshold (0.05 °C/min) in the search or adiabatic mode.

The APTAC HSS mode was also used. The sample was heated to a specified soaking temperature and held adiabatically. Every 60 min, or when the sample temperature rose 1 °C above the soaking temperature, the self-heating rate would be polled and compared with a pre-defined sensitivity threshold. If the self-heating rate exceeded the threshold, a runaway reaction was detected, and the sample was kept adiabatically. If the self-heating rate was less than the threshold, the sample would be cooled back to the soaking temperature. The steps were then continued for a defined period. If the system failed to detect self-heating at the end of the soaking period, it would proceed with a standard HWS mode. The HSS method is generally used to test the effectiveness of inhibitors added to the reactants.

The HWS mode was employed to determine the overall decomposition behavior of 24 mass-% HAN solutions, such as onset temperature (T_0), maximum temperature ($T_{\max}$), and maximum pressure ($P_{\max}$). The onset temperature in glass was 444 K (171 °C), in titanium it was 423 K (150 °C), and in stainless steel it was lowered substantially to 412 K (139 °C). The heat release was 23–43 kcal/mol and varied with the sample-container material used for the test.

The temperature curve of 24 mass-% HAN decomposition in the APTAC appears to consist of two stages: a slow initiation stage followed by a fast explosion stage. These two stages form a sharp discontinuity at the transition point. In contrast, for the decomposition of hydroxylamine free base, the temperature increase started immediately at the onset temperature and smoothly curved up to the maximum temperature. From comparison of the decomposition temperature curves, it was concluded that HAN decomposition is an autocatalytic reaction [415].

However, the autocatalytic decomposition behavior of HAN under runaway conditions has not been fully described by mathematical kinetic models because of its highly exothermic and rapid decomposition behavior. Additional work [414] focused on extracting HAN autocatalytic kinetics and analyzing HAN critical behavior from adiabatic calorimetry measurements. The heat of reaction of HAN measured by the APTAC was about 118 ± 20 kJ/mol, and the apparent activation energy was 82 ± 0.4 kJ/mol. The apparent activation energy of HAN decomposition depends on the aqueous solution concentration. Other authors [338] reported that the activation energies for 0.92 to 1.52-M HAN and for 1.58 to 1.74-M HAN solutions are 129 and 66 kJ/mol, respectively. A lumped autocatalytic kinetic model for HAN and associated model parameters were developed to describe rapid decomposition events. Critical conditions of diluted HAN solutions without the presence of catalytically active metal contaminants were bracketed. It would be interesting to repeat these tests for 81% HAN solutions, which are of primary interest for rocket propellants.

HAN solution isothermal decomposition measurements were performed in the temperature range of 353–433 K (80–160 °C) using an isothermal calorimeter equipped with a pressure-resistant glass reactor and an APTAC employing glass and titanium cells [98]. Reaction products were identified via UV, HPLC, and ion chromatography. An unidentified intermediate product was observed that is likely to be responsible for the observed autocatalytic behavior. This product was suspected to be an ammonia-related compound, such as NH_2^- or NH_2^- . Dilute aqueous solutions of HAN (<18% NH_3OHNO_3) were kept at constant temperature for different lengths of time in closed glass cells in an APTAC at 403, 413, and 423 K (130, 140, and 150 °C) and in a closed titanium cell at 433 K (160 °C). No evidence of HAN decomposition was observed at any temperature in the glass cells for the duration of the experiment, a period of approximately 1400 min. However, after approximately 800 min at 433 K (160 °C), the substrate in the titanium cell reacted in a very violent autocatalytic form to raise the pressure and the temperature of the system abruptly.

The addition of AN or HN to HAN improves its thermal stability. Such solutions are used as oxidizers (OXSOL-1, OXSOL-2, and S-HAN5). See also [287].

3.7.1 Storage Stability of Hydroxylammonium Nitrate Solutions

Storage stability deals with the thermal stability at room temperature. The chemical changes occur at a much slower rate than in an accelerated thermal stability test in DTA or DSC and are more difficult to measure. Fresh 24 mass-% HAN solutions without metal contamination can be safely stored and used at room temperature. However, under adverse conditions, HAN solutions can decompose at room temperature when the heat is not conducted away, and the reaction rate escalates to a runaway condition.

Following various incidents, extensive research included aging tests and adiabatic calorimetry of HAN solutions. Inverse-based fitting methods were combined to elucidate the aging and storage stability of HAN. Aqueous solutions of 18 mass-% HAN were subjected to aging tests and adiabatic decomposition tests at temperatures in the range of 303 to 433 K (30 to 160 °C), which covers the normal storage operation temperature and the onset temperatures under typical experimental conditions [416]. Furthermore, the influence of pressure, impurities, and temperature history profile were also examined. The liquid residue was analyzed at different stages of aging tests using HPLC. The experimental data were used to elucidate and deduce the mass-loss kinetics parameters. These data could be used to monitor the storage behavior of HAN.

The transportation hazard classification of 13-M HAN was based on the results of an instrumented dual-sample storage test with 50-g samples of 13-M HAN heated to 348 K (75 °C) for 48 h [417]. The test was later repeated with 100-g samples of 13-M HAN heated in an oven to 348 K (75 °C) for 48 h, which did not result in any noticeable changes of the material [418].

3.7.1.1 Effects of Contaminants on Storage Stability of Hydroxylammonium Nitrate Solutions

Many trace contaminants have a pronounced effect on the storability and thermal stability of HAN solutions (and HA free base). The most common contaminant is iron in the form of iron ions, which can be leached from processing equipment. In the case of reaction of HA and its salts with iron ions, Fe^{3+} was found to trigger an exothermic reaction [100]. Complexed iron in the form of $[\text{Fe}(\text{CN})_6]^{3-}$ was less reactive than free $\text{Fe}(\text{III})$ and $\text{Fe}(\text{EDTA})$.

The thermal decomposition behavior of HAN is influenced by starting materials and by-product metal salts or excess nitric acid that could get carried over into the final product during synthesis and purification [419, 420]. Comparing the thermal stability of HAN solution samples prepared by three different routes, it was observed that carryover of metal ions such as barium and calcium ions from the reactants and the by-products into HAN solution during preparation could influence the thermal and catalytic decomposition behavior of HAN as measured by DSC, TGA, and spot-plate tests. The decomposition mechanism of HAN was altered in the presence of barium and calcium ion impurities. Traces of nitric acid can lead to autodecomposition behavior of HAN during storage.

3.7.1.2 Stabilizers for Hydroxylammonium Nitrate Solutions

Stabilizers are typically complexing, chelating, and sequestering agents that inactivate transition metal ions that act as catalysts for HAN decomposition. Stabilizers for HAN solutions can be inorganic or organic compounds. For later use of the HAN as an oxidizer in monopropellants, organic additives would be preferred because they combust without leaving any residues. Some inorganic stabilizers (e.g., phosphates) leave undesirable residues that foul the catalysts. The use of stabilizers is of interest not only for the storage and transport of HAN solutions but also for the storage and transport of liquid propellants formulated with this oxidizer. Stabilizers for HAN-based monopropellants must work equally well regardless of the fuel contained in the mixture. In *Encyclopedia of Monopropellants*, chapter “Hydroxylammonium Nitrate-Based Monopropellants,” we summarize stabilizers tested with HAN-based monopropellants. More stabilizer studies have been done for HAN/TEAN/ H_2O mixtures than for any other propellant.

Several stabilizers patented for hydroxylamine free base would work just as well for HAN, including the trisodium salt of *N*-hydroxyethyl-ethylenediaminetriacetic acid, the tetrasodium salt of ethylenediaminetetraacetic acid, polyvinylpyrrolidone, and poly-*N*-vinyl-5-ethyl-oxalidinone [3].

Stabilizers tested at BRL include cupferron, ethylenediaminetetraacetic acid (EDTA), 1,2-diaminocyclohexanetetraacetic acid monohydrate (DCTA), 2,2'-dipyridyl, and tributylphosphate [421]. BRL researchers also tried removing contaminating transition-metal ions by adsorbing them onto ion exchange resins.

Stabilizers for HAN include pyridinium or pyridone salts, diphosphonates or methylenephosphonate salts, or their parent acids [422]. One of the stabilizers tested was the sodium salt of 2-hydroxypyridine-*N*-oxide. The effect of deliberate iron contamination (50 ppm Fe) and stabilizer addition (0.1%) on excess acid formation during storage of XM46 at 338 K (65 °C) is shown in Figure 49 (NaHPNO = sodium salt of 2-hydroxypyridine-*N*-oxide; NaMPNO = sodium salt of 2-mercaptopyridine-*N*-oxide). In addition to reduction of excess acid formation during storage, the onset of exotherms in DSC or ARC tests was also shifted to higher temperatures as the result of stabilizer addition. Other stabilizers proposed in this patent include diphosphonate or methylenephosphonate salts of the type aminotri(methylenephosphonic acid) and its corresponding pentasodium salt, which are commercially available from Monsanto under the trade names Dequest 2000 and Dequest 2006, respectively. Also patented was diethylenetriaminepenta(methylenephosphonic acid) and its corresponding hexasodium salt, commercially available from Monsanto under the trade names Dequest 2060 and Dequest 2066, respectively.

Figure 49: Effect of 50-ppm iron contamination and 0.1% stabilizers on excess acid formation of XM46 during storage at 338 K (65 °C). (Reproduced and modified from [422].)

The sodium salt of 2-hydroxypyridine-*N*-oxide in concentrations from about 10 ppm to about 1000 ppm in either pure HAN solutions or formulated propellants containing HAN and fuels has been patented as stabilizer [123]. Instead of sodium, it may be better to use the ammonium salts, lower alkylamine salts, or alkanolamine salts. Other stabilizers in this category are 2-hydroxy-4-methoxy-pyridine-*N*-oxide, 1,2-dimethyl-3-hydroxy-pyridine-4-one, 4-methyl-pyridine-*N*-oxide, 6-methyl-pyri-

dine-*N*-oxide, and 1-methyl-3-hydroxy-pyridine-2-one. After the effectiveness of this stabilizer was demonstrated for HAN by itself, it was also tested with XM46 [423].

The complexing agents cupferron, EDTA, DCTA, 2,2'-dipyridyl, and tributylphosphate were evaluated as stabilizers for HAN-based propellants [424, 425]. Other patents cover the use of hydroxylurea or hydroxythiourea derivatives as stabilizers for HAN solutions [426]. Suggested stabilizers for PERHAN were EDTA and cyclohexanediaminetetraacetic acid and their sodium salts [230]. Recommended stabilizers for HAN include diamine derivatives, ammonia derivatives, pyridine, and methylene phosphonic acid derivatives [427].

Insufficient storage stability for long service life in orbit is one of the problems with HAN monopropellants, and it is caused mostly by metal ions such as Fe^{3+} . Material compatibility tests showed that some metal ions get leached from the surface of propellant tanks and tubing. The decomposition of HAN is due to redox reactions between HAN and transition metal ions. Three chelating agents, hydroxyethylidene diphosphonic acid, diethylene triamine pentaacetic acid, and *N*-(2-hydroxyethyl)iminodiacetic acid, were selected and added to samples of 93% HAN solutions deliberately doped with Fe^{3+} ions in order to sequester the contaminant ions [428]. Three different molar ratios of chelating agent to Fe^{3+} were tested. When the solutions were examined using DTA-TGA before and after the addition of chelating agents to 93% HAN, the onset of thermal decomposition was shifted from 416 K (143 °C) to 438–444 K (165–171 °C). The burning rates of solutions before and after the addition of chelating agents were not much different, but addition of Fe^{3+} to HAN increased the burning rate. The chelating efficiency of different chelating agents strongly depended on the initial concentration of HAN solutions and was more effective in dilute solutions. Diethylene triamine pentaacetic acid had the best chelating capacity of the three agents tested.

3.8 Materials Compatibility with Hydroxylammonium Nitrate Solutions

There are two concerns about the compatibility of materials of construction with liquid-propellant ingredients. The first is the effect of the corrosive medium on the material, causing possible loss of structural integrity. The second is the effect of contaminants leached from the material of construction on the storage stability of the propellant. Much of the materials compatibility work was done during the RLPG effort for XM46 itself, but early tests often used only 60% HAN solutions as a substitute [429]. The argument was that the presence of fuels (regardless of which fuel is being used) does not significantly alter the corrosive behavior of the HAN/ H_2O system. The results of the materials compatibility tests with live XM46 or AF-M315E instead of HAN solution surrogates are discussed in *Encyclopedia of Monopropellants*, chapter “Hydroxylammonium Nitrate-Based Monopropellants.”

3.8.1 Compatibility of HAN Solutions with Metals

HAN solutions attack metals in two ways: first through the acidity of hydrolyzing salts of a weak base with a strong acid, and second by complexing the metal ions, thus continuously removing them from the galvanic equilibrium potential at the metal surface. Galvanic corrosion of dissimilar metals in contact with each other is the worst case; it might even qualify certain metal galvanic couples as a composition for a battery for generating electricity.

Fifty-one materials specimens (metals, polymers, and coated metals) were exposed to 61.7% HAN solution for 30 d at 298 K (25°C), and after three of them were eliminated, 48 specimens were exposed to 61.7% HAN solution for 30 d at 338 K (65°C) [430]. The samples were sealed under an argon atmosphere in a 50-mL glass ampoule connected to a mercury U-tube pressure gauge. A rubber septum allowed the withdrawal of gas samples for gas analysis and also allowed manual pressure-relief if the end of the mercury gauge pressure-measuring range was approached. The apparatus was immersed in a constant temperature bath such that only the rubber septums stayed above the oil level. The pressure was read daily. The test was continued for 30 d, or it was discontinued earlier if the rate of gas evolution exceeded 30 mm Hg/d. The pressure reading was converted to gas volume under standard (298 K, 1 atm) conditions. Typical coupon size was $5 \times 5 \times 1$ mm. The test coupons were weighed before and after the test, and weight changes were recorded as an indication of incompatibility. The iron, nickel, and copper samples had dissolved. At room temperature, only the samples listed in the upper part of Table 29 showed a measurable rate of gas evolution. Copper and iron were eliminated from high-temperature testing because their rate of gas evolution was unacceptable, even at room temperature. Table 29 lists the materials in the order of increasing gas-evolution rate (decreasing compatibility). Nitrogen and nitrous oxide were the only gases found by gas chromatography.

The compatibility of various materials of construction, including metals, alloys, plastics, and lubricants, with 60% HAN was determined by immersion tests at 298 K (25°C) and 338 K (65°C) under inert gas (argon) at Rocket Research Company, Redmond, WA (RRC) [429]. One hundred tests were performed on 48 government-furnished materials and two controls (HAN without any additive). Pressure rise during the 30-d tests was monitored daily as an indication of compatibility (or incompatibility). Post-test samples were examined for signs of corrosion, and some of the off-loaded propellant was analyzed for leached metals. At the end of the tests, the gas space above the samples was analyzed for chemical composition of the gases formed by drawing a gas sample with a hypodermic syringe needle inserted through a rubber-septum-sealed port at the top of the apparatus. This gas composition information can be useful for interpreting the mechanism of HAN decomposition due to incompatibility. The tests were conducted under argon instead of air so that all evolved gases (including oxygen, nitrogen, and hydrogen) could be analyzed by gas chromatography. Another reason for excluding air from the tests was that oxygen might have interacted with HAN and any corrosion processes in progress. An attempt to conduct the tests under

Table 29: Materials compatibility test results.

Material	Days in test	Volume of gas produced, cm ³			Gas evolution rate

Data source: [430]

helium instead of argon failed because the permeation rate of helium through the rubber septums was too high. The samples were totally immersed in 60% HAN in borosilicate glass ampoules connected to an open-ended mercury-filled U-gauge manometer open to the atmosphere and immersed in a constant temperature bath. The most significant weight loss was with Al-6061, which lost 1.57% at 298 K and 2.1% at 338 K. Silver solder had a weight loss of 9.6% at 298 K. The fastest rate of gas evolution was with Al-6061 (0.3 cm³/d at 298 K and 19.8 cm³/d at 338 K), silver solder, and Aeroshell 17 grease. The gas evolved from the Al-6061 sample contained up to 14% hydrogen. Hydrogen evolution during metals compatibility tests with HAN solutions had not been previously reported in the literature. The other surprise was the high carbon dioxide concentration when testing lubricants with HAN solutions. The highest carbon dioxide concentration, 75.6%, was observed with Aeroshell 14. The second highest carbon dioxide concentration, 57.6%, was found in a sample with 10W-30 motor oil. HAN appears to be a strong oxidizer comparable to concentrated nitric acid and can effectively destroy hydrocarbon bonds in oils and greases. It may be difficult to find a lubricant that is not affected, and additional work in this area may be required. In two of the oil samples, the mercury in the U-gauge turned black, and the presence of hydrogen sulfide in the gas space above the samples was proved by reaction with moist lead

acetate paper. Most of the samples tested (metallic and non-metallic) showed some reaction, and only a few materials emerged as compatible from this preliminary test. True compatibility would have to be proven by conducting tests extending beyond 30 d. The RRC report in the appendix contained the most complete database on HAN materials compatibility assembled to that date. This database was so complete that it was accepted in its entirety into the *JPL Liquid Propellant XM46 Handbook* [431].

It appears that the metal materials compatibility of HAN does not change significantly by adding TEAN or other fuels to the oxidizer solution. The relative ranking of metals tested in 13-M HAN or XM46 remained the same.

13-M HAN was used as a substitute for actual propellant mixtures in a series of materials compatibility tests at the NASA Glenn Research Center [432]. It was felt that because the majority of HAN-based propellants are 13-M HAN, and because the fuels (TEAN, glycine, or methanol) do not alter the results, this was a valid test method. In addition to 13-M, some testing was conducted with propellant blends called XM46, HAN204GLY, and HAN269MEO.

3.8.2 Compatibility of HAN Solutions with Elastomers

Several dozen polymer materials specimens were exposed to 61.7% HAN solution for 30 d at 298 K (25 °C) and 338 K (65 °C) [430]. Nylasint MA, Teflon 05-002, Rynite SST35, and Fluorocarbon 33 showed abnormally high rates of gas evolution and had to be eliminated from further testing.

3.8.3 Compatibility of HAN Solutions with Lubricants

The RLPG had many moving parts that needed to be lubricated to ensure operation without galling and metal particle abrasion. Under the fast and highly turbulent flow conditions, it was likely that some of the lubricants would be entrained into the flowing XM46 propellant. For rocket propulsion applications, there are only a few places that need lubrication that might come into contact with propellants. O-rings are often greased prior to installation to prevent damage during compression in the joint.

3.9 Safe Handling of Hydroxylammonium Nitrate Solutions

The recommended methods for the safe handling of HAN not only are of interest for the oxidizer solution itself for its production, storage, and shipping, but they apply equally to all propellants formulated with HAN.

3.9.1 Protective Clothing

The protective clothing to be worn when handling HAN solutions and HAN-based propellants is the same that would be worn when handling non-volatile acids such as sulfuric acids in lead-acid automotive batteries. Recommended protective clothing includes gloves, apron, face shield, and rubber boots.

After several candidate materials were evaluated in a permeability test apparatus, a polyurethane-coated polyester fabric was chosen to be the main material of the protective suit and hooded mask for HAN-based propellants [433]. Butyl rubber with a thickness of 0.40 mm was chosen as the material for protective gloves.

3.9.2 Fire Fighting

In separate tests, a 5-gallon and a 30-gallon polyethylene drum containing 13-M HAN were subjected to a bonfire test in accordance with U.S. Department of Transportation regulations as part of a test protocol to obtain a shipping permit. The test did not result in any explosions, and nothing was propelled from the burn pile.

3.9.3 Accident Investigations Involving Hydroxylammonium Nitrate

Since the 1970s, HAN has been involved in several incidents at several government facilities. On 14 May 1997, an incident occurred in the chemical preparation room of the Plutonium Reclamation Facility at the U.S. Department of Energy's Hanford Site Plutonium Finishing Plant near Richland, Washington [434]. HAN/HNO₃ solution had been stored in a steel tank (A-109) in the otherwise inactive facility for several years prior to the accident. The reaction created a rapid release of gases that built up pressure inside the tank. The pressure blew the lid off the tank, cut a fire-suppression water line, and damaged the roof and adjacent walls and doors. Water and spilled unreacted solution flooded the area and leaked into adjacent rooms. Residual plutonium leaked from the building as wastewater. The radioactive contamination outside the building was the result of acidic water flowing across contaminated walls and floors and extracting the radioactive salts. During the investigation, it was determined that the root causes of the incident were inadequate hazard evaluation, inadequate auditing of safety management systems, and inadequate training of personnel on reactive hazards [411]. A better understanding of materials compatibility of HAN solutions with tank materials would have prevented the accident.

A systematic approach was proposed to evaluate reactive chemical hazards. The first step of hazard evaluation is to use simple screening tools. For reactivity screening, the Molecular Orbital Package (MOPAC) and the ASTM Chemical Engineering Thermodynamics and Hazard Evaluation (CHETAH) have proven to be reliable and practical tools based on the analysis of 167 incidents reported by the Chemical Safety and Hazard Investigation Board. Until the Hanford incident, it was common practice to add concentrated nitric acid to dilute HAN solutions and store the solutions for some time for later use in nuclear fuel element reprocessing. Thermal stability and mixing tests in a calorimeter with 0.1, 0.25, and 0.5-M HNO₃ and 0, 0.05, 0.1, 0.2, 0.4, 0.7-M, and 1M-HAN showed that the heat release (41.7 cal/g HNO₃ at the highest concentrations tested) in these dilute solutions was solely due to heat of mixing and not to decomposition of HAN [435].

An autocatalytic reaction of HAN in HNO_3 solutions was studied by DTA methods to evaluate safety limits for the handling of HAN/ HNO_3 solutions as a plutonium reductant during the reprocessing of nuclear reactor fuel elements [436]. The initiation temperatures, onset of the autocatalytic reactions, were remarkably lowered with increasing HNO_3 and Fe^{3+} concentrations. By aging the solution, the threshold temperatures were further lowered because of an accumulation of HNO_3 produced from slow decomposition of HAN during storage.

3.10 Safety Properties of Hydroxylammonium Nitrate

The safety properties of 13-M HAN solutions were thoroughly investigated as part of obtaining a hazard classification and a shipping permit in the United States for this material [437]. The less concentrated solutions (24% HAN) had been shipped for several decades without any incidents before the more concentrated (13-M = 81% HAN) solutions became commercially available and required a new shipping permit.

3.10.1 Shock Sensitivity of Hydroxylammonium Nitrate Solutions

The shock sensitivity (cap sensitivity) of 13-M HAN was measured as part of its transportation hazard classification. The shock sensitivity of HAN solutions and other energetic materials depends on the energy density of the stimulus. The stimulus can be either a blasting cap (electric detonator) or it can come from a booster charge such as those employed in card-gap tests.

In addition to binary HAN solutions, two ternary solutions containing HAN, water, and AN or HN were also tested for impact sensitivity, cap sensitivity, card-gap sensitivity, and bullet-impact sensitivity, but no explosions were observed [438]. For both oxidizers, the drop-weight sensitivity was negative at 100 kg-cm, the cap sensitivity was negative with a J2 blasting cap, and the card-gap sensitivity was negative at zero cards. The bullet-impact sensitivity of OXSOL-1 was negative, but OXSOL-2 was susceptible to bullet impact in a steel tube of 2-in diameter.

3.10.2 Adiabatic Compression Sensitivity of Hydroxylammonium Nitrate Solutions

Unconfirmed reports indicate that 13-M HAN solutions gave a reaction when tested in the U-tube adiabatic compression test apparatus at 401 K (128 °C), while tests at 328, 348, and 373 K (55, 75, and 100 °C) were negative [439].

3.10.3 Cook-off Hazards of Hydroxylammonium Nitrate Solutions

The onset of exothermic reactions in HAN solutions was discussed extensively in Section 3.4.2. The direct consequence of this thermal instability is the cook-off hazard when storing and transporting HAN solutions. There have been several cook-off incidents,

although not all of these have been published. Section 3.9.3 is a summary of accident investigations of cook-off and spills with HAN solutions. A bonfire test with 13-M HAN was conducted as part of the hazardous material shipping classification [440, 441].

3.11 Toxicity of Hydroxylammonium Nitrate

Because one of the main motivations for developing HAN-based rocket propellants was the replacement of more toxic oxidizers and fuels with a “green,” environmentally friendly, non-toxic chemical, the toxicity of HAN and the fuels it was potentially combined with received a good amount of attention. People who were advocating the switch from hydrazine to green propellants wanted to make sure that there were no hidden hazards with HAN. Previous toxicity work was motivated by the proposed use of HAN-based propellants in torpedoes and liquid-propellant guns.

Because the main concern about current-technology hypergolic bipropellants (NTO/MMH) and monopropellants (N_2H_4 monopropellant) was the inhalation toxicity, it was welcome news when propellant chemists examined HAN solutions and noticed that this oxidizer has no measurable vapor pressure at all, and that whatever little vapor pressure is measurable is only that of innocuous water.

Hydroxylammonium nitrate is moderately toxic and mildly acidic. Toxicity studies include the potential oral ingestion, aerosol respiratory inhalation, and dermal resorption of propellant splashed on the skin. There are no reports (yet) of actual poisonings or propellant-handling accidents involving humans. All of the HAN toxicity information we have was obtained from animal tests. HAN can cause severe damage to skin, eyes, and red blood cells (RBCs) of the hematologic system. Significant signs of HAN poisoning include hemolytic anemia, methemoglobinemia, splenomegaly, erythrocyte destruction, and Heinz body formation [442]. Another HAN effect is brain ischemia, which is insufficient blood flow to the brain. Brain tissue samples of cerebral cortex, hippocampus, and cerebellum taken from Wistar rats injected with HAN solutions showed brain cell ischemia, unbalanced heme oxygenase, and induction of anoxia [443].

3.11.1 Acute Toxicity of HAN

The standard method of determining LD_{50} is by administering HAN in drinking water or in more concentrated doses by intraperitoneal injection (Table 30).

HAN was administered to male ICR mice at a dose of 120 mg/kg (below the LD_{50}) by intraperitoneal injection. The mice were killed on day 7 after intoxication, and the main organs were removed for pathologic examination [447]. Lung and liver tissues were severely injured. There was widespread pulmonary hemorrhage and severe lung tissue degeneration. Diffuse edema or ballooning degeneration occurred in the liver cells.

Table 30: Summary of LD₅₀ determinations of hydroxylammonium nitrate.

Test animal	Concentration	Mode of administration	LD ₅₀ , mg/kg body weight	References
Rat	13-M	Oral	325	[245]
Male ICR mice		Intraperitoneal	149.6	[444]
Male mice		Celiac artery	183–186	[445]
Wistar rats		Intraperitoneal	139.3	[446]

Both the acute and chronic (sub-chronic) toxicity and the response of main target organs to exposure to HAN were measured in a series of thorough animal-exposure tests [446]. In the acute-toxicity study, rats were administered different doses of HAN only once by intraperitoneal injection, and toxic signs and morbidity within 14 days were observed. In the sub-chronic study, rats were administered different daily doses of HAN (7, 14, or 28 mg/kg) or 0.9% saline for 13 weeks. After the last exposure, three-quarters of the rats were sacrificed. After the recovery and observation period, the remaining animals were sacrificed, and the main toxic target organs of sub-chronic exposure to HAN were evaluated. In the acute-toxicity study, the LD₅₀ of HAN in rats was 139.3 mg/kg, with a 95% confidence interval of 132.3–146.7 mg/kg. In the sub-chronic study, the body weight did not significantly change, but the spleen weights in all HAN-treated groups were significantly higher than those in the control group. Histopathologic observation showed that significant lesions mainly occurred in lung, liver, spleen, and kidney. HAN also caused a large amount of deposit of hemosiderin, especially in the liver, spleen, and kidney.

3.11.2 Inhalation Toxicity

HAN does not have a vapor pressure, thus there is no direct inhalation toxicity hazard. It would be very unlikely that personnel would be exposed to HAN aerosols. The main hazard would be the nitrous oxide and nitric acid fumes emanating from a HAN cook-off situation.

In order to evaluate the inhalation toxicity of XM46 and similar propellants, the inhalation toxicity of HAN solutions by themselves were also evaluated [448]. Rats and dogs were exposed to aerosolized HAN for 90 d at concentrations of 300, 100, or 33 mg/m³. Dose-related effects occurred in both species and documented themselves in rats by weight loss and spleen and liver enlargement. In dogs, respiratory irritation and blood dyscrasia were the major toxic effects observed. Minimal effects were observed at the low concentration, 33 mg/m³.

Personnel should be protected against all routes of HAN exposure since the systemic effects are additive. An airborne concentration of HAN of 3 mg/m³ was suggested as a basis for the development of a maximum allowable workplace atmosphere concentration.

Because HAN solutions do not have a measurable vapor pressure, the worst-case scenario was simulated by creating a HAN aerosol with a sprayer. For a sub-chronic toxicity study, groups of ten rats were exposed to 13.2-M HAN aerosols at three different concentrations (100, 300, or 600 mg/m³) for 6 h/day for 5 and 10 d [449]. At necropsy following the fifth day of exposure, both male and female rats exposed at 300 and 600 mg/m³ had enlarged spleens. Heinz body formation in erythrocytes was seen in both groups at the two highest doses tested. After 10 d, spleen weight to body weight ratios were increased, and liver ratios were decreased. RBC count, hematocrit, and hemoglobin levels were depressed after ten HAN exposures. The degree of severity of splenic hematopoiesis increased in the two high-treatment groups. Heinz body formation in RBCs is considered a valid index of systemic toxicity if workers at HAN factories or rocket test sites should become exposed to HAN aerosols.

When studying the inhalation toxicity of HAN solutions, one must make sure that the pH of the solution remains below 6. Above a pH of 8, there may be vapors of free hydroxylamine base in the vapor phase.

3.11.3 Blood Effects

HAN has adverse effects not only on RBCs already in circulation but also on the bone marrow where RBCs are generated and on reticulocytes that are about to become RBCs.

The effect of HAN exposure on micronucleus frequency of polychromatic erythrocytes from Wistar rats bone marrow was studied by administering different doses of HAN, 6.97, 13.93, or 27.86 mg/kg, to three treated groups by intraperitoneal injection, whereas a control group was treated only with 0.9% NaCl [450]. The treatment was performed every other day and continued for 90 d. After the last treatment on day 90, two-thirds of the rats were sacrificed, and after a 30-d observation period the remaining animals were sacrificed. The micronucleus frequency of bone marrow cells of Wistar rats treated by HAN was not significantly different from that of the control group, except for the highest dose group. After 30 d of recovery, the micronucleus frequency of HAN-treated animals was not significantly different from that of the control group.

The effect of HAN toxicity on the blood system in rats was studied by injecting Wistar rats with 75, 100, or 125 mg/kg, and blood samples were collected after 6 h, 1, 3, 7, 14, 28 d, 2, and 3 months [451]. Blood cell counts, erythrocyte fragility, Heinz body formation, and Howell-Jolly body formation were measured using a blood cell analyzer. The results showed that 6 h to 7 days after HAN injection, erythrocyte fragility, Heinz body formation, and Howell-Jolly body formation increased. RBC count, hematocrit (HCT), and hemoglobin (HGB) decreased, and mean corpuscular volume, mean corpuscular HGB, mean corpuscular HGB concentration, and RBC volume distribution width increased in a dose-dependent manner. The injection of HAN can obviously change the cell count and the structure and function of blood cells, especially for erythrocytes, and these changes are dose dependent.

Acute and sub-acute intraperitoneal administration of HAN solutions to Wistar rats resulted in decreased RBC counts and HGB levels and increased white blood cells (WBCs) at the end of the administration [452, 453]. A total of 160 rats were randomly divided into three HAN-treated groups and one control group. Each group included 40 rats. Different doses of HAN at 6.97, 13.93, or 27.86 mg/kg were administered to the three treated groups by intraperitoneal injection. The control group was injected with 0.9% saline. The treatment was continued every other day for 13 weeks. After the last treatment, 30 rats in each group were sacrificed, and the rest were kept another 4 weeks for observation. Hematologic parameters and reticulocyte and marrow cells were measured. For hematologic parameters, the main changes were decreases in RBC count and HGB level and an increase in WBCs at the end of the administration ($P < 0.05$). The reticulocyte values were obviously increased along with the increasing HAN dosage compared with those of the control group ($P < 0.01$). HAN has definite toxic effects on the blood system in rats for long term exposures.

The effects of HAN on superoxide dismutase (SOD), malondialdehyde (MDA), tumor necrosis factor- α (TNF- α), and interleukin-6 (IL-6) in rat serum were measured by administering different doses of HAN at 50, 75, or 100 mg/kg to three treated groups by intraperitoneal injection [454]. In parallel, a control group was treated only with 0.9% NaCl saline. After 24 h, a sample of blood was collected to measure the activity of SOD and the concentration of MDA, TNF- α , and IL-6. Reactive oxygen species (free radicals) degrade polyunsaturated lipids, forming MDA, which is a marker for oxidative stress. The activity of SOD fell with increasing dose size of HAN, and MDA concentration increased. Compared with the control group, each dose group was significantly different regarding the content of MDA. The groups dosed at 75 or 100 mg/kg were significantly different in SOD activity, and only the group exposed to a dose of 100 mg/kg exhibited a significant increase in TNF- α concentration ($P < 0.01$ and $P < 0.05$, respectively). The IL-6 concentration increased somewhat, but was not significantly different from that of the control group. The oxidative damage to serum enzymes might be one of the primary mechanisms of HAN toxicity. See also [455, 456].

The change of protein profiles in the serum of HAN-intoxicated mice was measured in order to obtain basic data to further explain the mechanism of HAN intoxication [457]. The animals in the HAN-intoxicated group were injected intraperitoneally with HAN ($LD_{20} = 158$ mg/kg), and the control group was injected with 0.9% saline. Serum samples from both groups were analyzed using surface-enhanced laser desorption/ionization time-of-flight mass spectrometry and protein chip technology. Adverse effects in mice in the HAN-intoxicated group included irritation of the respiratory tract and eyes, drooling, cyanosis, dyspnea, restlessness, and muscular shivering. Four different proteins were found in the serum of HAN-intoxicated mice group, which may be tell-tale signs of HAN intoxication.

3.11.4 Skin Effects

Application of HAN solutions to rabbit skin for 3 weeks induced a high incidence of chronic and ulcerative dermatitis in all treatment groups, including the group receiving the lowest dose tested, 0.7 mg/kg [458]. Higher doses (1.5–12 mg/kg) caused Heinz body formation and RBC destruction. It was recommended to avoid contact of HAN solutions with the skin and to wear gloves and splash-proof goggles when handling this material.

Hydroxylammonium sulfate is not used in rocket propellants, but because the toxic element in the salt is the hydroxylammonium ion and not the sulfate ion, information on its skin toxicity is included here. The acute toxicity of hydroxylammonium sulfate was tested in rabbits and rats following a single 24-h dermal exposure [459]. The test materials were applied topically and were occluded under a plastic or gauze cover or were injected subcutaneously. Hydroxylammonium sulfate produced hematotoxic effects similar to those of phenylhydrazine, consisting of methemoglobin formation, anemia, and reticulocytosis. It proved to be more toxic to rabbits than to rats, although both chemicals produced similar hematologic effects at equivalent dose-levels within the same species. Both were lethal to rabbits, but no deaths occurred among the rats. See also [460–462].

3.11.5 Mutagenic Effects

Many countries have invested a substantial amount of research efforts in the development of HAN-based propellants as replacements for more toxic propellants. The fear of inadvertently or unknowingly replacing one carcinogen with another led to a thorough examination of both the mutagenic and carcinogenic properties of hydroxylamine and its salts. Depending on the pH of the substrate, which was often buffered to maintain a constant pH, the tests may have included some free base or not. In discussing the mutagenicity of hydroxylamine and its salts, in particular HAN, there is some overlap between an earlier section (Section 1.8.2) and the current section.

The mutagenic potential of hydroxylammonium chloride NH_3OHCl was assessed in the Ames Salmonella/mammalian microsome mutagenicity test [463]. Tester strains TA97, TA98, TA100, TA102, TA1535, TA1537, and TA1538 were exposed to doses ranging from 0.2 mg/plate to 8.2×10^{-4} mg/plate. In this test, hydroxylammonium chloride produced a relatively high reversion rate at 2.5×10^{-3} mg/plate and 8.2×10^{-4} mg/plate in tester strain TA97, compared with the control (spontaneous revertant) plates. NH_3OHCl also produced a relatively high reversion rate at 0.2 mg/plate in tester strain TA1535. No mutagenic responses were observed for strains TA98, TA100, TA102, TA1537, or TA1538.

The effects of HAN on the *tk* gene of mouse lymphoma L5178Y cells were studied by treatment with HAN at different concentrations [464]. The cell-plating efficiency, relative suspension growth, and mutation frequency were determined. The results showed that HAN (50–500 $\mu\text{g/mL}$) induced *tk* gene mutation with mutation frequencies up to 19 times higher than that of the spontaneous mutation frequency of L5178Y cells.

After single celiac artery administration of HAN in mice, the mortality, chromosome aberration, micronuclei frequency, and physiologic changes of bone marrow cells were examined [445]. The LD₅₀ of HAN in male mice after 1 and 14 d was 186 mg/kg (185–187 mg/kg) and 183 mg/kg (182–184 mg/kg), respectively. No pathologic changes of the other organs were observed. There were significant changes in chromosome aberration and micronuclei rates in experimental groups compared with those of control group ($P < 0.05$). HAN is only a moderate mutagen, but it can induce some genetic damage of bone marrow cells.

3.11.6 Teratogenic Effects

The embryotoxicity of HAN and its teratogenic characteristics were studied by measuring the body weight, the death rate of fetuses, and the rate of absorbed embryos in exposed mice and a control group [465]. The external appearances, internal organs, and skeletons of the mouse embryos were observed. After the mice were given different doses of HAN, their weight, the number of living embryos, the number of absorbed embryos, and the number of dead embryos did not obviously change. The weight of the embryos did not change. There were no malformations in the skeletons of the mouse embryos, their exterior appearance, or their internal organs.

Testicular germ cell micronucleus tests, sperm deformity assay, and flow cytometry were used in order to study potential reproductive damage of testicular germ cells and sperm deformity induced by HAN in mice [466, 467]. It was shown that the percentage of deformities in sperm markedly increased as the dose increased ($P < 0.05$), and the percentage of micronuclei significantly decreased as the dose increased ($P < 0.05$). The damage to sperm could be correlated with the toxic exposure to HAN. The data suggest that HAN causes reproductive damage to testicular germ cells and sperm in mice.

3.11.7 Prophylaxis and Protection Against Accidental HAN Poisonings

People have asked whether there are any antidotes to accidental HAN poisoning; this was discussed as part of a survey on HAN toxicity and handling safety [468]. Prophylactic agents evaluated as antitoxins include squalene [469]. Squalene, an unsaturated hydrocarbon found in shark liver oil, may be a chemopreventive substance against cancer. Male mice were exposed to half the LD₅₀ of HAN by intraperitoneal infusion once per day for 3 d. The animals were divided into three groups: a normal control group, a HAN-treated group, and a HAN and squalene treatment group that was given 130 mg/kg squalene via gastric tube once per day for 7 d after the HAN poisoning. Squalene suppressed the HAN-induced reticulocyte and spleen hemosiderin increases and should be considered as an antidote to HAN poisoning.

Another potential therapy is treatment with methylthioninium chloride (methylene blue) [444]. Male ICR mice were poisoned by different concentrations of HAN. From this set of data, the LD₅₀ of HAN in mice was determined as a baseline

experiment and found to be 149.6 mg/kg body weight. Following HAN injection, methylthioninium chloride 9 mg/kg was injected intraperitoneally in one group of animals. The adverse effects and survival rates of the mice were observed continually for 7 d after injection. At the dosage of LD₅₀, the survival rate of the methylthioninium chloride therapeutic group was 56.5%, which indicates that methylthioninium chloride can antagonize HAN intoxication.

Another therapeutic treatment tested the antioxidant polyphenols from tea leaves (much touted as a cure-all for all ills that may have befallen modern society) [470]. An allotment of male ICR mice were divided into several groups: a control group, a HAN-poisoned group, an experimental group administered tea polyphenols before poisoning by HAN, and an experimental group administered tea polyphenols after poisoning by HAN. Peripheral hemocytology and serum biochemical parameters were measured, and it was shown that although HAN will increase WBCs; decrease RBCs, HGB, and platelet count; and cause serum biochemical parameters to deviate, tea polyphenols can help restore these abnormal values.

3.12 Environmental Effects of Hydroxylammonium Nitrate

Unlike PCB transformer oils or perchlorate ions, hydroxylamine and its salts do not constitute a chronic environmental hazard if spilled accidentally. They deteriorate quickly under the action of air, inorganic oxidants, and bacterial oxidation. Some bacteria even thrive on hydroxylamine, similar to ammonia as a nutrient. As discussed in detail in Section 1, hydroxylamine is an intermediate in the oxidation of ammonia to nitrite and in the reduction of nitrite to ammonia, and it occurs naturally in larger quantities than will ever be used as rocket propellant.

4 Hydroxylammonium Perchlorate

Hydroxylammonium perchlorate [NH₃OH][ClO₄], HAP, CAS RN [15588-62-2] is less water-soluble than the more frequently used HAN. A saturated solution of HAP in water at room temperature contains only 92% HAP, whereas a saturated solution of HAN in water contains 96% HAN. HAP contains 48.3% oxygen. HAP contains more oxygen than HAN, and the chlorine atom also will bind one hydrogen atom. This makes this oxidizer useful for applications in which the exhaust gases must be water soluble, such as in torpedo propellants (*Encyclopedia of Monopropellants*, chapter “Hydroxylammonium Nitrate-Based Monopropellants”).

Concentrated solutions of HAP can also be used as liquid oxidizers in bipropellant engines and hybrid rockets.

4.1 Preparation of Hydroxylammonium Perchlorate

Early investigators studied and patented the reaction of hydroxylammonium chloride with barium perchlorate in anhydrous ethanol. After removal of the barium chloride, the alcoholic solution was evaporated to dryness on a steam bath, extracted with diethyl ether (in which HAP is soluble), and the salt precipitated by addition of benzene [471, 472]:

However, barium chloride is not totally insoluble in ethanol, and the product is likely to contain barium. Precipitating barium sulfate instead of barium chloride would allow a more complete metathetical reaction by metathetical reaction of barium perchlorate and hydroxylammonium sulfate solutions, precipitating insoluble barium sulfate instead of barium chloride: [473]

The hydroxylammonium sulfate should be introduced in a slight excess, which can be removed with barium carbonate. The disadvantage is that the barium sulfate precipitates in very small particles with a high surface area that adsorbs a portion of the desired product. Preparing HAP by the metathetical reaction

in methanol solution would not be successful because sodium perchlorate and HAP are equally well soluble in methanol, and the reaction is an equilibrium that does not go to completion. The equilibrium can be shifted in the desired direction by gradually adding solvents in which sodium chloride is less soluble, followed by stepwise precipitating and removing the undesired NaCl. One such sequence adds n-butanol, removes the NaCl, drives off the methanol at low pressure, adds tert-butanol and isopropyl ether, removes the NaCl, drives off the solvents at low pressure, and finally adds methylene chloride to precipitate the HAP [474]. The NaCl salt cake can be washed with methanol to recover some of the HAP still adhering to the crystals. Another method described in the same patent uses a suspension of finely ground $[\text{NH}_3\text{OH}]_2[\text{SO}_4]$ in methanol, liberates the free hydroxylamine base by the addition of sodium hydroxide, removes the precipitated Na_2SO_4 , and neutralizes the free amine solution with 71% perchloric acid. The HAP is then separated from the methanol solution by the same solvent addition sequence as described for the process starting with the chloride instead of the sulfate.

Instead of using sodium hydroxide to liberate the free base from a suspension of finely ground $[\text{NH}_3\text{OH}]_2[\text{SO}_4]$ in methanol or ethanol, one can also use ammonia [160] to liberate hydroxylamine free base in an alcoholic solution and then neutralize it with perchloric acid or nitric acid to obtain HAP or HAN.

Cation-exchange reactions can use either cation-exchange resins or anion-exchange resins for the production of HAP [475]. If an anion-exchange resin is used, it could be loaded with hydroxyl ions from a caustic solution, a solution of hydroxylammonium chloride passed through the column to liberate the free hydroxylamine base, and the eluent neutralized with perchloric acid.

Another method is to load a cation-exchange resin with hydroxylammonium cations and then elute it with a solution of a perchlorate, preferably in a countercurrent flow arrangement [476].

Electrolytic reduction of nitric acid in perchloric acid solution can lead to HAP in a one-pot synthesis. HAP crystals are extremely hygroscopic, and it is difficult to crystallize them from aqueous solutions. In air at 18% relative humidity, crystals absorb enough water within 18 min to almost dissolve themselves in a deliquescent mess.

Improved packing densities can be achieved if the oxidizer for solid propellants is in spherical form and has a bimodal particle-size distribution. HAP and many other low-melting oxidizers can be prepared in spherical form by pouring a thin stream of the molten material (melting point $368\text{ K} = 95^\circ\text{C}$) into a cooling bath of an inert, high-boiling fluid, such as tetrachloroethylene [477]. The bath has a temperature gradient from top to bottom. The droplets assume spherical shapes by surface tension and solidify while they sink in the liquid.

It was also attempted to avoid the use of water as a solvent by heating a mixture of solid hydroxylammonium chloride with perchloric acid dihydrate, but premature decomposition occurred at the temperature required to drive off the hydrogen chloride [473].

A method suitable for preparation of research quantities of high-purity HAP in a reasonably short time consisted of reacting stoichiometric amounts of $\text{Ba}(\text{ClO}_4)_2$ and HONH_2Cl dissolved in absolute ethanol [478]. BaCl_2 precipitated and was filtered out, and the ethanol was removed in a flash evaporator. The solid HAP was dissolved in anhydrous diethyl ether; any residue filtered out, and the ether was then evaporated. This purification was repeated until no residue could be detected, at which point the HAP was precipitated from the solution with benzene. This material was dried in a glass dead-end tube for approximately 1 h at 343 K (70°C) and 6.7 Pa (0.05 mm Hg), at which point it usually assayed as $>97\%$ pure. Further purification by redissolving in ether and then reprecipitating with benzene and drying for 1 h at 343 K (70°C) and 6.7 Pa (0.05 mm Hg) gave a pure material well in excess of 99% purity, and the drying time was cut by a factor of 12 over that required formerly. Spot tests for Cl^- contamination were regularly negative.

The curing of PBAN binders in HAP-based solid propellants was prevented by premature interaction between the oxidizer and epoxy curing agents, such as Epon H-825. It was attempted to prevent oxidizer–binder interactions by coating HAP with phenylglycidyl ether or inerting HAP with toluene diisocyanate [479]. Substituting some of the HAP with AP also improved the curing of the binder.

4.2 Physical Properties of Hydroxylammonium Perchlorate

Solid HAP exists in three different phases [480]. The high-temperature form (phase B) melts at about 362–364 K (89–91 °C). A third phase (phase C) melts at about 331 K (58 °C) at atmospheric pressure. The HAP phase A crystals at 298 K (25 °C) have a density of 2.02 g/cm³, and the calculated X-ray density is 2.13 g/cm³ at 298 K (25 °C). Other sources have reported a density of 1.96 g/cm³. Physical properties of HAP are summarized in Table 31.

^aThe number reported by Zinovev and Zakharova [473] is much too low.

A near-saturated solution of HAP in water that was considered for torpedo applications contains 92 mass-% HAP. It is said to be used in underwater propulsion applications by the British Navy. It has a density of 1.71 g/cm³, a viscosity of 15 cPs, and a heat capacity of 1.84 J g^{–1} K^{–1}. The viscosity is almost double that of 13-M HAN solutions.

The freezing-point properties of HAP solutions are listed in a patent that describes the use of concentrated HAP solutions as liquid oxidizers in non-hypergolic bipropellant combinations to be used in rockets or underwater torpedoes (Table 32) [485].

The densities of 80–85 mass-% aqueous HAP solutions were determined, and the results are listed in Table 33.

A thermal stability test was performed on an 80%-by-weight aqueous HAP solution at 353 K (80 °C) for 30 d. The results indicated no pressure buildup, and the change in concentration of any of the components was negligible. DTA showed that exothermic decomposition of this oxidizer occurs above 483 K (210 °C). The sensitivity characteristics of 82.5 mass-% HAP solutions were investigated by several methods, and the

solutions were negative in the card-gap test at zero cards with the sample preheated to 298, 323, or 348 K (25, 50, or 75 °C).

4.2.1 Thermodynamic Properties of Hydroxylammonium Perchlorate

Data on the enthalpy of formation of HAP are in [85, 86]. The activation energy of the phase transition that occurs between 330 and 335 K (57 and 62 °C) is 241.4 kJ/mol (57.7 kcal/mol) [486].

In order to determine the enthalpy of formation of HAP, the combustion of HAP was carried out in an oxygen atmosphere using diethyl oxalate as the fuel [483]. The idealized reaction equation from which the heat of formation was calculated is as follows:

The energy of reaction at constant pressure and 25 °C is −788.88 kcal/mol. From that number the enthalpy of formation for crystalline HAP was derived as −276.8 ±

2.7 kJ/mol (-66.16 ± 0.65 kcal/mol). Other sources listed an enthalpy of formation of -278.2 kJ/mol.

4.2.2 Optical Properties of Hydroxylammonium Perchlorate

Infrared spectra of the solid chloride, bromide, iodide, nitrate, sulfate, and perchlorate of hydroxylamine were measured and compared to those of the deuterated salt analogs [282]. The iodide was less stable and could not be deuterated. All bands with the exception of the ν NO band and those of the anions are affected by deuteration (Table 34).

Table 34: Infrared absorption-band assignments for HAP spectra.

4.2.3 Molecular Structure of Hydroxylammonium Perchlorate

Solid HAP exists in three different phases, and phase transformations are accompanied by distinct changes in heat capacity and in cracking of previously well-crystallized large crystals. Some of the phase changes are not reversible. The crystal structure of the room-temperature form (phase A) has been determined, but in order to prevent phase changes, it was kept at 123.15 K (-150°C) during the experiment [487]. The high-temperature form (phase B), melting at about 362–364 K (89 – 91°C), was examined at 344 K (70°C). A third phase (phase C), which melts at about 331 K (58°C) at atmospheric pressure, was identified by heat-capacity measurements. Based on XRD, the HAP phase A crystals at 298 K (25°C) were found to be orthorhombic, with the cell dimensions $a = 7.52 \pm 0.02$ Å, $b = 7.14 \pm 0.01$ Å, $c = 15.99 \pm 0.02$ Å, and space group $P2_1cn$ or $Pmcn$. The structure consists of chains of perchlorate ion tetrahedra held together

by hydrogen bonding from parallel chains of NH_3OH^+ ions. The NH_3OH^+ ions may rotate around the N—O axis.

Based on neutron diffraction data, HAP crystallizes in the space group $P2_1cn$, and the cell parameters are $a = 7.52 \text{ \AA}$, $b = 7.14 \text{ \AA}$, $c = 15.99 \text{ \AA}$, and $Z = 8$ [488], in good agreement with XRD data. There is only hindered rotation of the $-\text{NH}_3$ group around the axis defined by the N—O bond.

High-pressure techniques were used to investigate polymorphism in energetic materials, and new high-pressure phases of HAP were structurally characterized using single-crystal X-ray and powder neutron diffraction [489]. Hydroxylammonium perchlorate has been investigated using high-temperature single-crystal X-ray diffraction and powder neutron diffraction, and a high-temperature phase has been fully structurally characterized for the first time. High-pressure studies of HAP indicated the presence of two new polymorphs.

4.3 Chemical Properties of Hydroxylammonium Perchlorate

Hydroxylammonium perchlorate forms solvate complexes with both one and two hydroxylamine molecules, $[\text{NH}_3\text{OH}][\text{ClO}_4] \cdot 2\text{NH}_2\text{OH}$ and $[\text{NH}_3\text{OH}][\text{ClO}_4] \cdot \text{NH}_2\text{OH}$, while the nitrate forms only a monoligand complex with one mol of hydroxylamine in its solvate sphere $[\text{NH}_3\text{OH}][\text{NO}_3] \cdot \text{NH}_2\text{OH}$ [295]. With the strong hydrogen bonding in the free base and in many of its salts, it is not surprising that the free base will attach itself as a solvate to some of its salts. Here is one example: 4.85 g (0.0365 mol) of $[\text{NH}_3\text{OH}][\text{ClO}_4]$ was dissolved in 300 mL of diethyl ether, and 20 mL of ethanol containing 1.21 g (0.0366 mol) of NH_2OH was added with stirring. The precipitate was filtered and dried to give a quantitative yield of the monohydroxylamine complex. These complexes are in general less hygroscopic than the salt itself. For instance, while the HAP gained 11.7 mass-% in 60 h at ambient conditions, its complexes showed no such weight gain. However, the dihydroxylamine complex was not stable, and when the recrystallized material was exposed to the atmosphere at room temperature, the dihydroxylamine complex lost one mol of hydroxylamine over a period of about 14 d, and the mono complex was obtained. The hydroxylammonium perchlorate monohydroxylamine was kept with no sign of moisture absorption or further decomposition at room temperature. The densities and DTA results of some of these complexes are summarized in Table 35.

Similar sparsely soluble complexes were obtained with LiClO_4 , $\text{Mg}(\text{ClO}_4)_2$, $\text{Ca}(\text{ClO}_4)_2$, and $\text{Ba}(\text{ClO}_4)_2$.

Regardless of the anion present, hydroxylammonium forms complexes with a number of transition metal salts, even in strongly acidic solutions. These complex salts include those with iron(II) [490] and vanadium(V) [491, 492]. The ligand in these complexes is free hydroxylamine in spite of the fact that the equilibrium concentration of the free base in strongly acidic solutions is only very small.

Table 35: Properties of complexes with hydroxylamine as the solvate.

Compound	Density, g/cm ³	Endotherms, start at °C	Exotherms, start at °C

4.4 Thermal Stability and Decomposition of Hydroxylammonium Perchlorate

Hydroxylammonium perchlorate has not found any applications in the solid state. Thermal decomposition studies have been performed for both solid crystals and aqueous solutions of this oxidizer.

The DTA thermogram of HAP showed exotherms at 451–493 K (178–220 °C) and 586–643 K (313–370 °C) and an endotherm starting at 793 K (520 °C) [473]. It is assumed that AP is an intermediate in the HAP decomposition.

Over the course of 6 years from 1962 through 1967 and under the sponsorship of the U.S. Air Force Office of Scientific Research with two consecutive contracts, Atlantic Research Corporation conducted a detailed investigation on the deflagration of high-energy solid oxidizers containing the perchlorate anion [493, 494], including ammonium perchlorate, hydrazinium(2+) diperchlorate, and HAP [481]. A similar program at Thiokol Reaction Motors Division studied hydrazinium(1+) perchlorate and HAP [478, 495]. Preliminary studies on the thermal decomposition of HAP indicated lower thermal stability than expected on the basis of literature reports. The autocatalytic nature of the reaction is apparent in the P vs. t plots at 403 and 413 K (130 and 140 °C). Mass spectrometric analyses of the gaseous products indicated 80% N₂O and 20% HCl. No other gaseous products were detected. Physical characteristics of the residue led to the suspicion that it may be hydrazinium perchlorate. Thermal decomposition rate experiments have been performed in the range from 393 to 433 K (120 to 160 °C), and the activation energy of the uncatalyzed reaction was found to be 185 kJ/mol (44.3 kcal/mol) [478]. In contrast to the HONH₃Cl decomposition reaction, no evidence of competing reactions was found. The volatile decomposition products have been identified as N₂O, HCl, and Cl₂. ClO₄[−], HONH₂, and NH₃ have been found in the highly acidic condensed residue, which is suspected to be a mixture of HAP, AP, and aqueous HClO₄. The thermal decomposition reactions of HAP were studied between 393 and 423 K (120 and 150 °C) in a sealed system and at 453 K (180 °C) in an open system [496]. For comparison, the thermal decomposition reactions of HONH₃Cl were studied in the temperature range 403–433 K (130–160 °C) to obtain an understanding of the decomposition reactions of hydroxylammonium ion free from external oxidants. The chloride was found to decompose by two mechanisms, and the reaction of the

perchlorate was found to undergo similar initiating steps, but the presence of excess oxidant increased the reaction rate and led to a different stoichiometry.

Mass spectroscopic analysis of decomposition products during slow ramp-up thermal analysis was used to study the thermal decomposition of hydroxylammonium and methoxyammonium perchlorates [486, 497]. The first step in the thermal decomposition of these salts is the proton transfer from the substituted ammonium ion to the perchlorate anion to form the free substituted amine and perchloric acid. An activation energy of $241 \pm 29 \text{ kJ/mol}$ ($57.7 \pm 7 \text{ kcal/mol}$) was calculated for the transition from the slope of the line below 273 K (0 °C). Once the crystalline phase transition is complete, dissociation of the solid HAP continues smoothly to its melting point at 353 K (80 °C). Slow dissociation (proton transfer) begins below and continues to its melting point at 353 K (80 °C). The activation energy of the dissociation process

is 86.6 kJ/mol (20.7 kcal/mol) when based on NH_2OH measurements, but it is 194 kJ/mol (46.4 kcal/mol) when the calculation is based on the ClO_3^- concentration measured with the mass spectrometer in the gas space above the sample. The latter number is similar to breaking the $\text{HO}-\text{ClO}_3$ bond energy in HClO_4 , which is 188 kJ/mol (45 kcal/mol). In comparison, the O-methylhydroxylammonium perchlorate has no phase transitions in the solid state between 326 and 350 K (53 and 77 °C). The activation energy calculated from the slope of the free H_3CONH_2 base is 125 kJ/mol ($30 \pm 2 \text{ kcal/mol}$) and that from the slope of the ClO_3^- ion is 185 kJ/mol ($44.2 \pm 2 \text{ kcal/mol}$), similar to the $\text{NH}_3\text{OHClO}_4$ value. H_3CONH_2 is a stronger base than HONH_2 .

An examination of the compatibility and stability characteristics of HAP and hydrazinium(2+) diperchlorate (HP-2) and the inherent reactivities of the oxidizers with several types of organic substances showed that both are relatively weak oxidizers, with HP-2 being slightly more reactive than HAP and both being more reactive than AP [498]. Both oxidizers react prematurely with candidate binders in solid propellants, in particular with isocyanates, which complicates the preparation of solid propellants with these oxidizers.

The vapor species evolved from subliming HAP at 383–393 K (110–120 °C) were trapped in a frozen matrix and analyzed by IR absorption spectrometry [499]. The sublimation and decomposition of HAP in comparison to AP, methylammonium perchlorate, and hydrazinium(1+) perchlorate examined by a cold matrix isolation–infrared spectroscopic technique was shown to vaporize by dissociation. IR spectra of the frozen matrix showed individual free hydroxylamine and perchloric acid. This observation supports the proton transfer theory as the initiating step of HAP decomposition. Other species observed were water and nitrous oxide. In a comparison of the vaporization temperatures of HAP, AP, HP, and methylammonium perchlorate, the relative vaporization temperatures could be correlated with the pK values of the bases in aqueous solution. The spectrum of the vapor species from HAP at 393 K (120 °C) clearly showed perchloric acid, and the bands at 3640, 1604, 1364, 1132, and

893 cm^{-1} agreed well with the hydroxylamine free base gas-phase bands of Giguere and Liu 1952 [38] at 3656 , 1605 , 1125 , 1115 , and 896 cm^{-1} if small matrix shifts are permitted.

One of the possible decomposition reactions is

but this reaction has not yet been balanced for stoichiometry. The residue of partially decomposed samples contains AP. Samples that have completely decomposed satisfy the stoichiometry of equation

The products of the decomposition of HAP include NH_4ClO_4 , N_2O , H_2O , HClO_4 , Cl_2 , HCl , O_2 , and unidentified oxides of chlorine [500]. The rate of decomposition is quite slow below the melting point.

A reversible $10.46\text{--}12.55\text{ J/g}$ ($2.5\text{--}3.0\text{ cal/g}$) endotherm was observed with HAP at $\sim 333\text{ K}$ ($\sim 60^\circ\text{C}$) and considered to be a phase transformation [501]. The $<0.2\%$ mass loss associated with the transformation was explained by a release of volatiles through crystal relaxation. The possibility that the endotherm resulted from impurity melting was considered as well, but the absence of any associated freezing exotherm and the time delay in recovery when the sample was cooled were more consistent with a crystal phase change. The melting endotherm reappeared upon successive heating at 368 K ($\sim 95^\circ\text{C}$). When the molten material was cooled, a sharp freezing exotherm was visible as either a large single peak or two smaller peaks between 329 and 336 K (56 and 63°C). The water that was detected in the mass spectra of HAP probably came from adsorbed moisture due to the hygroscopic nature of HAP.

At low degrees of conversion, the rate of gas evolution from decomposing HAP decreases until it reaches a constant value [502]. Addition of hydroxylammonium sulfate slows down the decomposition. Addition of sequestering agents capable of complexing transition metal cations improves the stability of HAP by one order of magnitude.

HAP forms an adduct with free hydroxylamine $\text{HONH}_3\text{ClO}_4 \bullet \text{NH}_2\text{OH}$, CAS RN [25417-72-5] [503–505]. The effect of the addition of guanidine or HAP and of dilution with H_2O , MeOH , or EtOH on the burning rate was also investigated. The decomposition of the adduct involves monomolecular dissociation, and a decomposition of the HAP and free NH_2OH base thus formed. The decomposition products contain ammonia, which displaces NH_2OH from the adduct.

4.5 Reactions of Hydroxylammonium Perchlorate

Studies of the stability of HAP and its compatibility with binders and curing agents showed that HAP was less reactive than HP-2 but more reactive than AP [506]. Binders investigated included hydroxyl- and carboxy-terminated polybutadiene and

polyisobutylene prepolymers, as well as poly-1,2-bis(difluoroamino)-2,3-propylene oxide (P-BEP). Binder prepolymers studied were hydroxyl terminated polyisobutylene (UTREZ-diol), carboxyl terminated UTREZ, hydroxyl terminated polybutadiene (R-45-M), carboxyl terminated polybutadiene (Telagen CT), saturated hydroxyl terminated Telagen, a carboxyl terminated polyisobutylene (EMD-590), and two ethyl acrylate–acrylic acid copolymers. The curing agents studied included isocyanates, an aziridine (MAPS), and an epoxide (ERLA-4221). Parallel studies of hydrazinium(2+) diperchlorate (HP-2) and AP were included to provide a baseline for comparing the relative merits of the more energetic oxidizers. Later in the program, and after HP-2 was essentially eliminated as a candidate oxidizer, the compatibility of HAP with two NF plasticizers, 1,2,3-tris[1,2-bis(difluoroamino)]ethoxy propane (TVOPA) and 2,3-bis(difluoroamino)-propyl-2,2-dinitropropylcarbonate (P-722), and with aluminum hydride (LMH-1) were studied. HAP, which was slightly more attractive from a compatibility viewpoint than HP-2, was carried along as a candidate advanced oxidizer.

4.5.1 Reaction of HAP and HClO_4

HAP does not form an adduct with excess perchloric acid [507]. To 0.267 g (2mmol) of HAP at -196°C , approximately 2mL of anhydrous HClO_4 was added. The reaction mixture was allowed to warm to room temperature. After 15 min of stirring at ambient temperatures, the excess HClO_4 was slowly removed in a vacuum. The $\text{NH}_3\text{OHClO}_4$ was found to be unchanged on the basis of XRD analysis.

4.5.2 Reaction of HAP and Nitrate Esters

HAP solutions have been considered as oxidizers to be injected into Otto Fuel II exhaust gases in torpedoes to increase the performance, remove soot, and reduce the non-condensable gases in the wake of the torpedo. It has been considered to store the two immiscible fluids in the same propellant tank, but they are not compatible and cannot be stored in contact with each other. Headspace gas analysis has shown that nitrous oxide is the principal gas evolved during contact between Otto Fuel II and 82 mass-% aqueous HAP solution at temperatures close to ambient [508–510]. The gas was produced mainly from the 82% HAP layer and was generated in significant amounts only after the Otto Fuel II had already become blackened as a result of extreme degradation. The pH of the HAP solution fell during contact with Otto Fuel II, and the Otto Fuel II blackening point was the same for each of three storage temperatures investigated, indicating that the production of N_2O may depend upon the attainment of a specific HAP solution acidity. It was suggested that the propylene glycol dinitrate (PGDN) component in Otto Fuel II undergoes acid hydrolysis at the liquid/liquid interface and that the nitric acid produced leads to the decrease in HAP solution pH and to stabilizer depletion in Otto Fuel II. Experiments involving contact between 82% HAP and the other components of Otto Fuel II confirm the key role of PGDN: In its

absence there was no change in HAP solution acidity, no gas evolution, and no violent reaction between the two liquids.

Gas chromatography with a flame ionization detector was used to determine changes in the concentrations of the components of Otto Fuel II in contact with 82% aqueous solution of HAP in sealed glass vials at 31.7°C during the period leading up to autoignition of the two incompatible liquids [511]. The concentration of hydroxylamine in HAP was monitored over the same period using a titration method. It was found that 2-nitrodiphenylamine (2-NDPA), the stabilizer in Otto Fuel II, was completely consumed after about 65–70 h and that the concentration of hydroxylamine began to fall at this point. 1,2-propanediol dinitrate (propylene glycol dinitrate, PGDN), the energetic component in Otto Fuel II, was not depleted significantly until after about 90 h. The evolution of nitrous oxide (N_2O) between 65 and 90 h is attributed to the reaction of the hydroxylammonium ion with nitrous acids produced by PGDN decomposition at the liquid–liquid interface.

4.6 Strand Burning Rates of Hydroxylammonium Perchlorate

The strand burning behavior of HAP and other perchlorate salts was studied in a series of research contracts at Atlantic Research Corporation under the sponsorship of the U.S. Air Force [481, 512, 513]. HAP powder was either gently tamped into Pyrex tubes (bulk density $\rho = 1.10 \text{ g/cm}^3$) or pressed into pellets ($\rho = 2.05 \text{ g/cm}^3$). The combustion was somewhat luminous and formed a foamy molten layer on the surface. The lower pressure limit for stable deflagration was at 13.6 MPa (135 atm) for HAP tamped into 8-mm diameter tubes. There was a lot of scatter in the burning-rate data at pressures below 20.2 MPa (200 atm). Burning rates at 15.15 MPa (150 atm) varied from 2 to 4 cm/s. Due to the data scatter, a burning-rate coefficient could not be obtained for pressures below 20.2 MPa (200 atm). At higher pressures, the burning rate coefficient was 0.52. Results of tests with HAP in different diameter tubes suggested that HAP will not sustain combustion below 10.1 MPa (100 atm), even with very large samples. The burning rate of HAP increased with tube diameters ranging from 3.8 to 8 mm.

The deflagration of solid HAP has been studied at pressures of 21–6900 kPa (3–1000 psia) and compared to that of AP and HNF. HAP exhibited a low-pressure deflagration limit of 14.75 MPa (146 atm), analogous to the 2.02 MPa (20 atm) limit of AP [514]. This high value was obtained in spite of a flame temperature for HAP that is 100° higher than that of AP, and despite the fact that at pressures at which HAP does burn, it burns two to three times more rapidly than AP does. A comparison of results for several oxidizers suggested that AP should be regarded as exhibiting an unusually low low-pressure limit.

The pressure dependence of the strand burning rate of HAP as well as of HAP/AP mixtures and non-stoichiometric HAP/free HA and HAP/ HClO_4 adducts was deter-

mined in 7-mm ID tubes at 0.1 to 13.1 MPa (1 to 130 atm) [515]. HAP by itself burned unstably and had a discontinuity in the $r_b = f(p)$ curve in the range of 3–10.1 MPa (30–100 atm). In the intermediate range, combustion is either impossible or is troubled by quenching and pressure pulsations. Small (0.1%) HClO_4 additions inhibited HAP over a wide range, but larger (0.4 and 0.6% HClO_4) additions increased the burning rate by a factor of 1.5 over a wide range of pressures and lifted it out of the discontinuity shown by pure HAP. At least 10% AP addition was required to get HAP/AP mixtures to burn over the entire range of pressures tested. The HAP/HA adduct burned stably at pressures from 100 mm Hg to 130 atm. It burned much faster than HAP by itself. The pressure dependence of the temperature coefficient was also measured for all samples.

4.7 Handling and Safety Properties of Hydroxylammonium Perchlorate

Dry HAP is very sensitive to impact in the drop-weight test with a 2-kg weight in the U.S. Bureau of Mines apparatus (50% point at 15 cm [471]).

4.8 Detonability of Hydroxylammonium Perchlorate Solutions

The detonability of aqueous solutions/suspensions of organic amine perchlorates and HAP was studied in steel and glass ampoules with an electric detonator with or without an intermediate hexogen booster. The isochoric detonation temperature of aqueous solutions of HAP was 680–860 K, and the upper concentration limit of H_2O below which the solutions retained their detonation capacity was 20–25% H_2O [516].

Hydroxylammonium perchlorate solutions have been proposed as a liquid explosive [517], as well as in mixtures with ethanolammonium perchlorate (monoethanolammonium perchlorate, MEAP). Solutions of HAP were found to have an especially high tendency to propagate detonation by low-velocity detonation (LVD) [518, 519]. Explosives that are sensitive to LVD are not very safe to handle, since a minor shock may cause them to explode, particularly in the presence of gas bubbles. Both HAP and MEAP are quite soluble in water. It is thus possible to create fairly concentrated detonable solutions without any suspended solids. The tests were done in moderate confinement (glass tubes) and heavy confinement (steel pipes). High-velocity detonation could be achieved only for larger diameters and with heavy confinement. Two mixtures with different HAP:MEAP molar ratios were studied in more detail: a mixture with a HAP:MEAP molar ratio of 4:1 and one with a ratio of 4:5. The mixtures have a very small critical diameter, below which detonation does not propagate. The critical diameter of two HAP/MEAP mixtures is shown in Figure 50 as a function of the amount of water diluent. The critical diameter of the more energetic mixture (4:5 molar ratio) may be as small as 2 mm.

Figure 50: Critical diameter of HAP/MEAP explosives as a function of water content. (Republished and modified from [518], with permission of Springer Nature BV © 1988; permission conveyed through Copyright Clearance Center Inc.)

Circles: 4:5 mixture. Triangles = 4:1 mixture. Solid symbols: Detonation positive. Open symbols: Detonation failed.

The critical diameter as a function of the O:F mixture ratio goes through a minimum at 1.4 mm for the most energetic 4:5 mixture (Figure 51). Additional tests were conducted in which the explosive was gelled and aerated such that small bubbles were trapped. Such bubbles form hot spots when suddenly compressed. The detonation velocity was dependent on pipe diameter but was not very dependent on the degree of aeration or the charge density. The highest detonation velocity measured in steel pipes was 6200 m/s. For tests in glass tubes, the detonation velocity dropped sharply below a certain concentration of air bubbles.

In the NOL Large Scale Gap Test, HAP packed to a density of 0.97 g/cm^3 had a sensitivity of 363 cards (50% point), corresponding to an attenuated shock pressure of 6 kbar [520].

Figure 51: Critical diameter of HAP/MEAP explosives with 9–12% water as a function of mixture ratio. (Republished and modified from [518], with permission of Springer Nature BV © 1988; permission conveyed through Copyright Clearance Center Inc.)

Solid symbols: Detonation positive. Open circles: Detonation failed.

4.9 Applications of Hydroxylammonium Perchlorate

Hydroxylammonium perchlorate has been evaluated as an oxidizer in solid-propellant formulations. Thiokol developed HAP-based solid propellants in the 1960s, but the work was discontinued after interest waned [521].

The burning rate of AP/polysulfide solid propellants can be increased significantly by adding as little as 5% HAP [472]. Similar results were obtained with hydrazinium(1+) perchlorate and semicarbazide perchlorate.

HAP has been evaluated as an oxidizer in solid-propellant formulations with various binders. Efforts to prepare HAP/P-BPE (a domino binder)/AlH₃ propellants were not successful [522].

Composite solid propellants containing HAP, also in the form of AP/HAP mixtures and with a variety of conventional binders, including isocyanate-cured HTPB with or without the addition of aluminum powder, have been patented [521].

Water-soluble polymers (polyvinyl alcohol, polyvinyl pyrrolidone) are also soluble in molten HAP or molten HAN, forming a castable solid propellant that is actually a solid solution [523]. Instead of mixing the binder into the molten oxidizer, both oxidizer and binder can be first dissolved in methanol, mixed, and the solvent evaporated. Increased specific impulse can be achieved by incorporating up to 20% aluminum powder in the formulation. High-temperature safety tests indicated that the dry molten HAP process for preparing the solid solution was not suitable for scaling up to pound-size batches in larger mixers.

The performance of Otto Fuel II in torpedo drives can be increased by 40% on a mass basis and 66% on a volume basis by injecting a HAP solution into the hot exhaust [524]. The injection of HAP solutions into Otto Fuel II exhaust not only increases the performance but also cleans up the exhaust and burns up all the soot. It has been considered to store the two immiscible fluids in the same container, but they are not compatible and cannot be stored in contact with each other (Section 4.5.2). HAP solutions have also been proposed as an oxidizer for bipropellant-powered torpedoes [525] and in monopropellants with dioxane or glycerol as the fuel [526].

5 Other Hydroxylammonium Salts

5.1 Hydroxylammonium Dinitramide

Hydroxylammonium dinitramide, $[\text{NH}_3\text{OH}][\text{N}(\text{NO}_2)_2]$, HADN, if it existed in the pure state, would have a better oxygen balance at +34.27% than ADN, with +25.79%. It contains 2.14 g-atom oxygen/100 g of salt. It appears that the only compound known with a structure similar to HADN is an adduct that contains a mol of free hydroxylamine as a solvate, which has an oxygen balance of only +23.11%.

5.1.1 Preparation of Hydroxylammonium Dinitramide

Hydroxylammonium dinitramide was prepared by ion exchange from a column loaded with dinitramide ions.

5.1.2 Physical Properties of Hydroxylammonium Dinitramide

5.1.2.1 Melting Point and Phase Diagrams of Hydroxylammonium Dinitramide

Hydroxylammonium dinitramide does not crystallize readily at room temperature. In one literature reference, HADN is described as a liquid. In another reference, a melting point is given as 291–296 K (18–23 °C) [527, 528]. It is not certain that these investigators had a pure substance. In both cases, HADN appears to be a room-temperature ionic liquid.

5.1.2.2 Density and Partial Molar Volumes of Hydroxylammonium Dinitramide

The X-ray density of HADN is $\rho_c = 1.859 \text{ g/cm}^3$ [529]. Pycnometric density measurements indicated a lower density of 1.733 g/cm^3 at 293 K.

5.1.2.3 Thermodynamic Properties and Thermal Properties of Hydroxylammonium Dinitramide

The predicted enthalpy of formation of HADN is $-144.3 \text{ kJ/mol} = -34.5 \text{ kcal/mol}$.

5.1.2.4 Molecular Properties of Hydroxylammonium Dinitramide

Hydroxylammonium dinitramide crystallizes in the orthorhombic space group *Pcab* (non-standard setting of *Pbca*) with cell dimensions $a = 6.439(2)$, $b = 12.470(4)$, $c = 30.816(14) \text{ \AA}$, $Z = 8$, and $\rho_c = 1.859 \text{ g/cm}^3$ [529]. In HADN there are both neutral and zwitterionic hydroxylamine moieties involved in the hydrogen-bonding scheme. The complete formula unit is $[\text{NH}_3^+\text{OH}]_2[\text{N}_3\text{O}_4^-]_2 \cdot (\text{NH}_2\text{OH}) \cdot (\text{NH}_3^+\text{O}^-)$, and in this structure the hydroxylamine exists in three possible forms: protonated, neutral, and zwitterionic. In these structures, the conformations adopted by the dinitramine anions can be related to the types of hydrogen bonds formed with the surrounding amine cations. Atomic coordinates, bond lengths and angles, and equivalent isotropic displacement parameters for the salts have been calculated and tabulated. These cations provide a constrained local environment for the dinitramide anions due to extensive hydrogen bonding.

5.1.3 Chemistry of Hydroxylammonium Dinitramide

Hydroxylammonium dinitramide is miscible with acetonitrile, dimethylformamide, nitromethane, and methanol.

5.1.3.1 Thermal Stability of Hydroxylammonium Dinitramide

In DSC, HADN begins to decompose at 407 K (134°C), compared to an onset of exotherm of 413 K (140°C) for ADN. The activation energy of HADN decomposition is 117 kJ/mol (28 kcal/mol).

5.1.4 Explosive and Fire Hazards of Hydroxylammonium Dinitramide

A compound described as SRI-14 is a hydroxylammonium dinitramide containing some free hydroxylamine as a solvate with a gross formula of $\text{N}_5\text{H}_7\text{O}_6$. It is a solid that melts at 357 K (84°C) and is less soluble in water (42%) than ADN (70%), both saturated at 273 K (0°C). The impact sensitivity of SRI-14 was found to be approximately 3–4 J (16–20 cm with a 2-kg weight), which is in the same range as that of ADN [530].

5.2 Hydroxylammonium Azide

Hydroxylammonium azide solvated with an extra mol of hydroxylamine free base can be prepared by reaction of trimethylsilyl azide with ammonium fluoride in methanol: [531]

The same method can also be used for preparation of hydrazinium(1+) azide or ammonium azide. It melts at 337 K (64 °C) and begins to decompose exothermically, with a peak at 387 K (114 °C). The theoretical density calculated from XRD data is 1.611 g/cm³.

6 Alkylhydroxylammonium Salts

One, two, or three hydrogen atoms on hydroxylamine can be substituted by alkyl groups on either the N-atom or the O-atom or both. When writing the name “alkylhydroxylamine,” one must always indicate the location where the alkyl substitution has taken place. Both types of substituted derivatives and their salts are known [532]. The most frequently used substituent is the methyl group, leading to the isomers *O*-methylhydroxylamine and *N*-methylhydroxylamine:

Both groups of compounds are potential rocket propellants, either in the form of the free base or in the form of their salts with oxidizing acids, such as nitrates and perchlorates.

The length of the alkyl group will rarely exceed two carbon atoms, so the energy contributed by the —NHOH group is not too diluted. Methyl substituted hydroxylamines are the ones examined most frequently as potential rocket propellants. They have a combustible alkyl group and an oxygen-carrying group in the same molecule and would make potential monopropellants.

In trying to decide whether the *O*-alkylhydroxylamines or *N*-alkylhydroxylamines should be discussed first, it was arbitrarily decided to do the *O*-alkyl hydroxylamine compounds first and the *N*-alkyl compounds last.

6.1 *O*-Methylhydroxylamine

O-methylhydroxylamine, hydroxylamine, *O*-methyl-; methoxyamine, $\text{H}_3\text{C}-\text{O}-\text{NH}_2$, $\text{C}_1\text{H}_5\text{N}_1\text{O}_1$, CAS RN [67-62-9], is sometimes also called methoxyamine. It forms stable salts with many acids, including nitric acid and perchloric acid. The free base and the chloride salt are commercially available, although the prices seem unreasonable. Isomers of *O*-methyl hydroxylamine are *N*-methyl hydroxylamine and aminomethanol $\text{H}_2\text{NCH}_2\text{OH}$.

6.1.1 Preparation of *O*-Methylhydroxylamine

O-alkylhydroxylamines can be prepared by reaction of chloramine with sodium alcoholate of the alcohol intended as the alkyl rest [533].

O-methylhydroxylammonium chloride can be prepared by alkylating potassium hydroxylaminedisulfonate with dimethyl sulfate or by reaction of sulfamic acid $\text{NH}_2\text{OSO}_3\text{H}$ with sodium alcoholates in alcohols containing a polar aprotic solvent [534]. Thus, 3.0 mol NaOMe in 378 g MeOH was added over 30 min at $<283\text{ K}$ ($<10^\circ\text{C}$) to a suspension of 1.0 mol $\text{NH}_2\text{OSO}_3\text{H}$ in 1200 g MeCN, and the mixture was stirred 3 h at 293 K (20°). NH_2OMe was distilled off at 313 K (40°C) and 20 kPa (200 mbar) and treated with acids to make the desired salt.

Another process obtains *O*-methylhydroxylamine by reacting an alkali metal salt of hydroxylaminedisulfonic acid with an alkyl chloride to form an alkali metal salt of an *O*-substituted hydroxylaminedisulfonic acid, which will then be hydrolyzed [535]. Thus, methyl chloride was added to a mixture of hydroxylaminedisulfonic acid disodium salt and 50% NaOH in a pressure vessel, and the resulting mixture was stirred at 323 K (50°C) for 2 h to give a product containing *O*-methylhydroxylaminedisulfonic acid disodium salt, which was hydrolyzed with sulfuric acid and then neutralized with aqueous NaOH to give *O*-methylhydroxylamine by distillation with a boiling point of 322 K (49°C) in 80% yield.

O-methylhydroxylamine in mixtures with other fuels has been proposed as a rocket fuel [536].

6.1.2 Physical Properties of *O*-Methylhydroxylamine

The boiling point of *O*-methylhydroxylamine is 322.6 K (49.5°C). The density of *O*-methylhydroxylamine at 293 K is 0.9069 g/cm^3 [537]. *O*-methylhydroxylamine has a melting point of 186.7 K (-86.4°C), a boiling point of 321.2 K (48.1°C), a heat of evaporation of 32.2 kJ/mol (7.71 kcal/mol), and a Trouton constant of 24.0 [538]. The vapor pressure of *O*-methylhydroxylamine can be calculated from

$$\log P = -2433.7/T + 23.9284 - 5.3746 \log T$$

where P is the pressure in mmHg and T is the temperature in kelvin. The basicity constant pK_b of *O*-methylhydroxylamine at infinite dilution is $pK_b = 9.25 \pm 0.02$; this compares to 8.04 ± 0.02 for the *N*-methylhydroxylamine isomer.

The IR spectra of CH_3ONH_2 , CH_3OND_2 , $\text{CH}_3\text{ONH}_3\text{Cl}$, and $\text{CH}_3\text{OND}_3\text{Cl}$ were obtained in the region $4000\text{--}400\text{ cm}^{-1}$ with the samples in the form of thin crystalline films at liquid nitrogen temperature [539]. With the exception of the CH_3 and NH_3^+ torsions, all the fundamentals for methoxyamine and methoxyammonium ion have been observed and assigned. The assignments for $\text{CH}_3\text{ONH}_3^+$ ion were readily correlated with those for CH_3ONH_2 , and for both species the assignments for the A' vibrations were consistent with the product rule.

The liquid state IR spectra of the *O*-alkylhydroxylamines $n - \text{C}_n\text{H}_{2n+1}\text{ONH}_2$, $n = 1, 2, 4, 6, 8$, or 10 in the range $3650\text{--}375\text{ cm}^{-1}$ and the Raman spectra of the compounds $n = 1, 6, 8$, or 10 were measured and compared for assignment of the absorption bands to molecular vibrations [540].

6.1.3 Chemical Properties of *O*-Methylhydroxylamine

O-methylhydroxylamine H_3CONH_2 , with a pK_a of 4.66 ± 0.70 , is a stronger base than hydroxylamine HONH_2 . The positive induction effect of alkyl groups causes a higher basicity of aliphatic amines with respect to ammonia, but the alkylation of hydroxylamine brings about a decrease in the pK_a values of alkylhydroxylamines in comparison with hydroxylamine. This effect was described in earlier literature but remained without explanation until it was examined again in 1975 [541]. *N*-alkylated hydroxylamines were stronger bases than *O*-alkylated hydroxylamines due to hydrogen-bonding effects.

6.1.3.1 *O*-Substituted Hydroxylammonium Salts

The melting point of *O*-methylhydroxylammonium chloride is $422\text{--}423\text{ K}$ ($149\text{--}150^\circ\text{C}$). The melting point of *O*-ethylhydroxylammonium chloride is $398\text{--}399\text{ K}$ ($125\text{--}126^\circ\text{C}$). The boiling point of the *O*-ethylhydroxylamine free base is 342 K (69°C).

6.1.3.2 *O*-Methylhydroxylammonium Nitrate

O-methylhydroxylammonium nitrate, MAN, $\text{H}_3\text{CON}^+\text{H}_3\text{ NO}_3^-$, $\text{C}_1\text{H}_6\text{N}_2\text{O}_4$, with a molecular mass of 110.069 g/mol and an oxygen balance of -14.5% , is a candidate ingredient for water-soluble monopropellants.

The salts of methoxyamine were evaluated as additives to hydrazine to produce low-freezing storable monopropellants. Further investigation of these salts as propellant constituents was done in ternary systems, adding H_2O as an additional freezing point depressant so that the salt content could be kept at a safer level.

6.1.3.3 Toxicity of *O*-Methylhydroxylammonium Nitrate

In vitro rat hepatocyte toxicity and bacteria (*Salmonella*) genotoxicity assays were performed on 13 high-energy chemicals that are candidates for potential replacement monopropellants for hydrazine [542]. The chemicals were mostly hydrazine derivatives and amino compounds in the form of their nitrate salts. The results in hepatocytes showed a dose-dependent decrease in mitochondrial activity, an increase in lactate dehydrogenase leakage, and depletion of GSH levels. *O*-methylhydroxylammonium nitrate displayed medium toxicity (HDN > EAN > MAN). Results of genotoxicity tests (Ames assay) indicated that *O*-methylhydroxylammonium nitrate is mutagenic.

6.1.3.4 *O*-Methylhydroxylammonium Perchlorate

O-Methylhydroxylammonium perchlorate, methoxyammonium perchlorate, MAP, $\text{H}_3\text{CON}^+\text{H}_3\text{ClO}_4^-$, $\text{C}_1\text{H}_6\text{N}_1\text{O}_4\text{Cl}$, with a molecular mass of 147.51 g/mol, was a candidate ingredient for monopropellants, but its shock sensitivity prevented further work on the pure compound. Mass spectroscopic analysis of decomposition products during slow ramp-up thermal analysis was used to study the thermal decomposition of methoxyammonium perchlorate [486]. The activation energy for the dissociation of methoxyammonium perchlorate was 125 kJ/mol between 326 and 350 K (30 kcal/mol, 53 to 77 °C).

6.2 Methylenedioxyamine

Not just one but two hydrogens on methane can be replaced by oxyamino groups, leading to $\text{H}_2\text{N}-\text{O}-\text{CH}_2-\text{O}-\text{NH}_2$, methylenedioxyamine, which forms stable salts with strong acids.

Other authors have called this compound methylene**b**isoxamine, but it is our understanding of chemical nomenclature that bis and tris and tetrakis as prefixes are to be used only if the rest of the name already contains di or tri or tetra to indicate the presence of two, three, or four substituents or in the word tridecyl or tetradecyl. The International Union of Pure and Applied Chemistry (IUPAC) nomenclature rules state, “However, the multiplying prefixes ‘bis-’, ‘tris-’, etc., are used instead of ‘di-’, ‘tri-’, etc., when the use of the latter would result in a potential ambiguity.” *Chemical Abstracts* uses a two-part nomenclature that may be systematic but is not very convenient, e.g., hydroxylamine, *O,O'*-methylenebis-. Such nomenclature is suitable for an index but not for running text. If conducting a literature search, one will have to search under both names, methylenedioxyamine and methylenebisoxamine. The name may also have been split into two words: methylene bisoxamine or ethylene bisoxamine. The location of the bonds between the heteroatoms and the carbon skeleton is not always indicated, but it could be *O,O'* or *N,N'*.

O,O'-methylenedioxyamine, also known as *O,O'*-methylenedioxamine, *O,O'*-methylenebisoxamine, MBO; hydroxylamine, *O,O'*-methylenebis-; $\text{H}_2\text{N}-\text{O}-\text{CH}_2-\text{O}-\text{NH}_2$, $\text{C}_1\text{H}_6\text{N}_2\text{O}_2$, CAS RN [40770-44-3], is not very stable as the free base, but it is stable enough to be distilled under vacuum. It can be prepared by hydrolysis of methylene-*O,O'*-di(ethylacethydroximate) with hydrochloric acid in diglyme as the solvent, isolation as the hydrochloride, followed by hydrolysis of the chloride salt solution and liberation of the free base by reaction with alcoholic sodium hydroxide [543]. The preparation of the methylenedioxyamine precursor is described in [544]. The free base is a colorless oil with a freezing point of 265 to 264 K (−8 to −9°C) and a boiling point of 340 K (67°C) at 3 mm Hg. The free base can be distilled under vacuum at 340 K/0.4 kPa (67°C/3 mm Hg). Methylenedioxyamine is a slightly viscous liquid with a refractive index $n_D = 1.4625$, which is thermally stable when pure to 443 K (170°C). At temperatures above 443 K (170°C), detonation can occur. Its melting point is approximately 273 K (0°C); however, it tends to form a viscous liquid or glass when cooled below that temperature. The heat of formation is −92 kJ/mol (−22 kcal/mol), and the drop-weight sensitivity is $H_{50} = 60$ kg-cm.

6.2.1 *O*-Methylenedioxyamine Salts

Normally, if an $-\text{NH}_2$ group is protonated to become a cation, the new compound is an ammonium salt, called methylammonium nitrate and not methylamine nitrate. In the case of methoxyamines, this nomenclature rule has not always been followed, and the name of the unprotonated hydroxylamine has been kept in several publications. Several methylenedioxyamine salts have been prepared and proposed as potential rocket propellants [545]. The salts described in the patent literature [546] include the methylenedioxyamine diperchlorate, with a melting point of 388 K (115°C).

The monoprotonated and diprotonated salts of methylene dioxyamine with nitric acid, perchloric acid, trinitromethane, and dinitramidic acid have been prepared as crystalline materials and characterized by DSC, IR, Raman, NMR, and elemental analysis [547–549]. The methylene dioxyamine mononitrate was obtained as colorless crystals with a melting point of 385 K (112°C) and the dinitrate with a melting point of 403 K (130°C). Methylene dioxyamine monoperchlorate was obtained as colorless crystals with a melting point of 404 K (131°C), and the diperchlorate melted at 400 K (127°C). With nitroform, only the monoprotonated salt could be formed. Methylene dioxyamine mononitroformate was obtained as bright yellow crystals with a melting point of 380 K (107°C). The colorless crystals of methylene dioxyamine monodinitramide melted at 369 K (96°C), and the methylene dioxyamine bisdinitramide melted at 358–368 K (85–95°C). The drop-weight sensitivity of the methylene dioxyamine bisdinitramide was less than 5 kg-cm, indicating that this is a very sensitive compound. Friction sensitivity of the monoperchlorate and the monodinitramide salt was less than 0.45 kg_f, indicating that these are indeed extremely sensitive compounds that should not be scaled up to larger-scale preparation.

6.2.2 Methylenedioxyamine Diperchlorate (DOAP)

If the hydrolysis of methylene-*O,O'*-di(ethylacethydroximate) is conducted with perchloric acid instead of hydrochloric acid, one obtains the diperchlorate salt, which has a density of 2.0 g/cm³ and a drop-weight sensitivity of $H_{50} = 110$ kg-cm and melts at 391 K (118 °C) [546]. The enthalpy of formation of the diperchlorate salt is -431 kJ/mol (-103 kcal/mol) [550].

Methylenedioxyamine diperchlorate $[\text{H}_3\text{N}^+ - \text{O} - \text{CH}_2 - \text{O} - \text{N}^+\text{H}_3][\text{ClO}_4^-]_2$, $\text{C}_4\text{H}_{10}\text{N}_2\text{O}_4\text{Cl}_2$, has been prepared and its thermal stability studied by thermal analysis (DTA/TGA), with simultaneous identification of the off-gassing by mass spectrometry [551]. The initial step in the thermal decomposition of DOAP occurred at 333 K (60 °C) with the loss of a perchloric acid group to form the monoperchlorate salt as an intermediate. As the temperature increased, the latter underwent a concerted cyclization-cleavage reaction leading to formamide and HAP. The existence of each of the postulated intermediates in the reaction was verified by separate experiments.

A sample of the vacuum-dried DOAP liquefied in the dry box after standing at ambient temperature for 2 weeks [506]. The thermal stability of DOAP was studied at 298, 313, 333, and 353 K (25, 40, 60, and 80 °C). While both HAP and HP-2 showed only trace amounts of gaseous decomposition products after 72 d at 343 K (70 °C), DOAP liberated 2–3 mL of gas per gram at 333 K (60 °C) in 32 d and 13–20 mL at 333 K (60 °C) in 90 d. The gaseous product consisted mainly of CO and lesser amounts of N₂, CO₂, and N₂O.

6.2.3 Other Methylenedioxyamine Salts

Other methylenedioxyamine salts claimed but not characterized included the dinitrate, the dinitroformate, and the dipicrate. Combining this energetic amine with energetic anions from acids like dinitramide

led to an interesting high-energy material, O-methylene dioxammonium(2+) bis-dinitramide, which has not yet found any applications [545]. It was reported to be a colorless oil at room temperature with a melting point of 293 K (20 °C). Repeated studies preparing the salt via cation exchange and neutralization of the free base obtained a purer product in the form of white crystals melting at 368 K (95 °C). The product was very shock sensitive (<5 kg-cm in the drop-weight tester, detonating with a light hammer blow) and had an onset of exotherm at 376 K (103 °C) in DSC [545]. The researchers also synthesized the monodinitramide salt, which had similar properties, melting at 359 K (96 °C), having a drop-weight sensitivity of 12 kg-cm, and showing the onset of an exotherm at 392 K (119 °C).

6.3 *O,O'*-Ethylenedioxyamine

Homologs of the compound *O*-methylenedioxyamine described in the preceding section are *O,O'*-ethylenedioxyamine, also known as *O,O'*-ethylenebisoxamine, ethylene di(oxyamine), 1,2-di(oxyamino)ethane; hydroxylamine, *O*-[2-(aminooxy)ethyl]-; $\text{H}_2\text{NOCH}_2\text{CH}_2\text{ONH}_2$, $\text{C}_2\text{H}_8\text{N}_2\text{O}_2$, CAS RN [5627-11-2] and *O,O'*-propylenedioxyamine, also known as *O,O'*-propylenebisoxamine, 1,3-di(oxyamino)propane; hydroxylamine, *O,O'*-1,3-propanediylbis-; $\text{H}_2\text{NOCH}_2\text{CH}_2\text{CH}_2\text{ONH}_2$, $\text{C}_3\text{H}_{10}\text{N}_2\text{O}_2$, CAS RN [98627-69-1], obtained by adding one or two more $-\text{CH}_2-$ groups.

1,2-di(oxyamino)ethane free base is a solid at room temperature that melts at 398–407 K (125–134 °C) and decomposes at 407 K (134 °C). 1,2-di(oxyamino)ethane-based energetic ionic liquids (EILs) belong to a group of salts that fail to meet the IL designation.

The synthesis, characterization, theoretical performance calculations, and safety properties of energetic salts based on 1,2-di(oxyamino)ethane, ($\text{H}_2\text{NOCH}_2\text{CH}_2\text{ONH}_2$), were investigated, and the salts were characterized by IR, Raman, multi-nuclear (^1H , ^{13}C) NMR, DSC, and elemental analysis, as well as by impact and friction-sensitivity testing [552, 553]. The crystal structures of the monoperchlorate and the double-nitrate salts were identified by single-crystal XRD (Table 36).

The salts with nitrate, perchlorate, trinitroformate, and dinitramidate as the anion behave as ionic liquids and are extremely shock sensitive [554]. In almost all cases, ethylene di(oxyamine) salts were extremely sensitive to impact and friction, often with quite spectacular results being observed, including loud responses and the shearing of the entire steel-pin apparatus on both the drop-weight tester and the friction tester.

1,3-di(oxyamino)propane is a relatively stable liquid with a boiling point of 338–343 K (65–70 °C) at 0.3 mmHg and a glass point of 233 K (–40 °C). The monoprotonated and diprotonated nitrate, perchlorate, and dinitramidate salts of *O,O'*-ethylenebisoxamine were prepared and characterized [555]. Ethylene di(oxyamine) bis(dinitramide) did not crystallize. After workup under vacuum, a viscous straw-colored ionic liquid had been evacuated to a constant weight. The dinitrate salt was a crystalline solid with acceptable properties, but the diperchlorate was very sensitive. The properties of these salts are summarized in Table 36, 37, and 38.

O,O'-ethylenedi(oxyamine) bisdinitramidate melts below 273 K, qualifying it as a room-temperature ionic liquid. Its decomposition temperature is $T_{\text{dec}} = 388 - 393 = 115 - 120$ °C, the impact sensitivity is 20 kg-cm, and the friction sensitivity is $< 4.4 \text{ N} = < 0.45 \text{ kg}_f$. However, this compound proved to be very sensitive, having a highly explosive response and completely destroying the scratcher from the Julius Peters-style friction tester.

The most stable ionic liquid was *O,O'*-ethylenedi(oxyamine) mononitrate, $[\text{H}_2\text{NOCH}_2\text{CH}_2\text{ONH}_3][\text{NO}_3]$, $\text{C}_2\text{H}_9\text{N}_3\text{O}_5$, with a melting point of $T_{\text{melt}} = 346 - 349 = 73 - 76$ °C, a decomposition onset of $T_{\text{dec}} = 353 \pm 80$ °C, impact sensitivity of 94 kg-cm,

Table 36: Properties of energetic salts of *O,O'*-ethylene di(oxyamine).

Note: Values with * had a highly explosive response, destroying the striker or scratcher completely.

Data source: [553]

and a friction sensitivity of 224 N = 22.8 kg_f; showing less impact sensitivity (in the Olin Matheson–style drop-weight tester with a 2-kg mass) than the HMX standard (impact sensitivity 34 kg-cm).

6.4 1,3-Propylene-*O,O'*-dihydroxylamine

1,3-propylene-*O,O'*-dihydroxylamine, also known as 1,3-bis(oxyamine)propane; 1,3-propanediamine, *O,O'*-dihydroxy-; hydroxylamine, *O,O'*-1,3-propanediylbis-; H₂N–O–CH₂–CH₂–CH₂–O–NH₂, C₃H₁₀N₂O₂, CAS RN [98627-69-1], is a reactant for preparation of energetic salts. The free base 1,3-di(oxyamine)propane boils at 338–343 K (65–70 °C) at 0.3 mm Hg and solidifies to a glass at 233 K (–40 °C).

The nitrate, perchlorate, trinitromethide, and dinitramidate salts of this compound have very low melting points, which classify them as ionic liquids.

They are extremely shock sensitive and could not be used as rocket propellants [554]. This compound forms complexes with metal ions and has been evaluated for pharmaceutical purposes.

6.5 *N*-Methylhydroxylamine

N-methylhydroxylamine; also known as hydroxylamine, *N*-methyl; *N*-hydroxymethanamine, methylhydroxylamine, *N*-hydroxymethylamine, *N*-methylhydroxylamine, H_3CNHOH , $\text{C}_1\text{H}_5\text{N}_1\text{O}_1$, CAS RN [593-77-1], is an isomer of *O*-methylhydroxylamine and aminomethanol $\text{H}_2\text{NCH}_2\text{OH}$. *N*-methylhydroxylamine can be used as an oxygen scavenger in boiler feedwater treatment as a replacement for hydrazine hydrate.

6.5.1 Preparation of *N*-Methylhydroxylamine

N-methylhydroxylamine can be prepared by hydrogenation of nitromethane in 3.5- N H_2SO_4 at 35–40° in the presence of poisoned Pt/C catalysts [557], in the presence of a palladium catalyst, [558] or by electrolytic reduction of nitromethane in aqueous solution. Synthesis of *N*-methylhydroxylamine by electroreduction of nitromethane can be carried out in aqueous acidic medium with Monel, nickel, stainless steel, or lead cathodes and anodes separated by a cation-exchange membrane [559]. The electroreduction of nitromethane can also be carried out on mercury cathodes [560], on gold electrodes [561], or on Cu and Cu/Hg as the cathode [562].

6.5.2 Physical Properties of *N*-Methylhydroxylamine

N-methylhydroxylamine has a melting point of 311.6 K (38.5°C), a boiling point of 388 K (115.0°C), a heat of evaporation of 49.7 kJ/mol (11.88 kcal/mol), and a Trouton constant of 30.6 [538]. The vapor pressure of solid *N*-methylhydroxylamine can be calculated from

$$\log P = \frac{13.7}{T} - 4.261 + 5.63 \times 10^{-5} T$$

and the vapor pressure of molten *N*-methylhydroxylamine can be calculated from

$$\log P = -\frac{2597}{T} + 9.570$$

where P is the pressure in mmHg and T is the temperature in kelvin. The $\text{p}K_{\text{b}}$ of *N*-methylhydroxylamine at infinite dilution is 8.04 ± 0.02 ; this compares to $\text{p}K_{\text{b}} = 9.25 \pm 0.02$ for the *O*-methylhydroxylamine isomer.

6.5.3 Molecular Structures of *N*-Methylhydroxylamine and Isomers

Alkylation of the NH_2 group in hydroxylamine changes the proton-transfer barriers. The physical properties of HAN solutions are determined by hydrogen bonding and proton transfer between neutral molecules and ion clusters in the ionic liquid structure. The effects of alkyl (CH_3 or C_2H_5) substitutions for hydrogen on the proton-transfer barriers in ammonium nitrate and HAN were studied using *ab initio* electronic structure calculations [563]. The optimized hydrogen-bonded neutral-pair structures and the ion-pair transition states for proton transfer were calculated. Zero-point energies, basis-set superposition corrections, and single-point MP2 calculations on the optimized structures were applied to obtain binding energies for these hydrogen-bonded molecules. The alkyl substituents strengthen the hydrogen bonding in both the neutral-pair and ion-pair complexes, but the ion-pair forms are stabilized to a greater extent, which results in an effective decrease in the barrier to proton transfer and exchange. The energy barrier to proton transfer in AN is 33.89 kJ/mol (8.1 kcal/mol), whereas in methylammonium, ethylammonium, and dimethylammonium nitrate, this barrier decreases to 17.15, 15.48, and 5.86 kJ/mol (4.1, 3.7, and 1.4 kcal/mol), respectively. Alkyl substitution reduces the proton-transfer barrier, and dialkyl substitution reduces it even further. A similar trend holds for HAN and *N*-methylhydroxylammonium nitrate: The barrier to proton transfer from the most stable neutral-pair HAN to the lowest-energy ion-pair configuration is 56.9 kJ/mol (13.6 kcal/mol), whereas this barrier decreases to 39.75 kJ/mol (9.5 kcal/mol) in the corresponding MeHAN complex.

Computer calculations were performed to predict the heat capacity, enthalpy, entropy, bond lengths, and bond angles of MeONH_2 , HONHMe , and HONMe_2 [564].

Electron-diffraction studies showed that MeNHOR and R_2NOMe ($\text{R} = \text{H}, \text{Me}$) exist in two conformations differing by a 180° rotation about the $\text{N}-\text{O}$ bond, as previously predicted by MO calculations, but with a much smaller free-energy difference (~ 2.5 kJ/mol = ~ 0.6 kcal/mol) than that predicted by calculations (~ 29 – 46 kJ/mol = ~ 7 – 11 kcal/mol) [565].

Gas-phase He(I) photoelectron spectra were measured for H_2NOH and the five methylhydroxylamines [566]. To study the interactions of the $n(\text{N})$ and $n(\text{O})$ orbitals, MINDO/2 calculations were performed for various conformations of the hydroxylamines. The *trans* forms are the most stable conformations, but *cis* conformers cannot be excluded.

The MNDO/H approximation has been used to calculate bond lengths, effective atomic charges and bond orders, and some physicochemical properties of methyl derivatives of hydroxylamine [567].

Molecular orbital calculations showed that hydroxylamine and methylated hydroxylamines exist in two conformations that are 11.7–26.3 kJ/mol (2.8–6.3 kcal/mol) apart in energy and that the length of the $\text{N}-\text{O}$ bond does not change upon methylation [568].

6.5.4 *N*-Methylhydroxylammonium Salts

N-methylhydroxylamine can be imagined as *N*-methylation of NH_2OH or by replacing a hydrogen in methane CH_4 by an $-\text{NHOH}$ group. In carrying the synthesis of energetic salts by replacing hydrogen on methane by hydroxylamino groups one step further, not just one but two hydrogens on methane can be replaced by hydroxylamino groups, and the resulting methylene dihydroxylamine can form useful oxidizer salts with perchloric acid.

6.5.5 Methylene dioxyammonium Salts

Instead of substituting only one hydrogen atom in methane with an NHOH group, up to two hydrogen atoms in methane can be substituted with hydroxylamine groups, and the di(hydroxylamino)methane can be reacted with diluted perchloric acid, making an even better oxidizer than *O*-methylhydroxylammonium perchlorate. *N,N'*-methylene dihydroxylamine, also known as methylene bishydroxylamine, di(oxyamine)methane; methanediamine, *N,N'*-dihydroxy-; $\text{HO}-\text{NH}-\text{CH}_2-\text{NH}-\text{OH}$, $\text{C}_1\text{H}_6\text{N}_2\text{O}_2$, CAS RN [4410-93-9], is not very stable as the free base, but the free base and several of its salts have been prepared and evaluated as propellant ingredients [569, 570]. The heat of formation of methylene dioxyamine diperchlorate dissolved in ethylene glycol was determined by oxygen bomb calorimetry as -437 kJ/mol (-104.4 kcal/mol) [571]. The heats of formation of methylene dioxyamine and methylene dioxyamine diperchlorate were derived from oxygen bomb combustion calorimetry and solution calorimetry [572]. Selected best values for the two compounds were -94.6 kJ/mol (-22.6 kcal/mol) for liquid methylene dioxyamine and -431 kJ/mol (-103.0 kcal/mol) for crystalline methylene dioxyamine diperchlorate.

6.6 1,2-Ethane di(*N*-hydroxylammonium) Nitrate

Similar to the methylenedioxyamine, hydroxylamino groups can be introduced in both the 1-position and the 2-position of ethane to form 1,2-ethanedioxyamine; 1,2-ethanediamine, *N,N'*-dihydroxy-; $\text{HO}-\text{NH}-\text{CH}_2-\text{CH}_2-\text{NH}-\text{OH}$, $\text{C}_2\text{H}_8\text{N}_2\text{O}_2$, CAS RN [30718-86-6], also called 1,2-ethylenedioxyamine. The parent free base is not very stable, but its salts have been prepared and characterized. The melting point of 1,2-ethane di(*N*-hydroxylammonium) nitrate

is below room temperature, and it is difficult to get it to crystallize. It is a perfect ionic liquid, except its thermal stability and shock sensitivity are less than optimal. The density of the melt is 1.93 g/cm^3 . Its oxygen balance is -29.3% .

For the preparation of ethylene dihydroxylamine, 1,2-ethylene-*N,N'*-dihydroxylamine, 1,2-di(hydroxylamino)ethane, $\text{HO}-\text{NH}-\text{CH}_2-\text{CH}_2-\text{NH}-\text{OH}$,

the intermediate 1,2-bis(phthalimidooxy)ethane was first prepared via the treatment of 1,2-dibromoethane with *N*-hydroxyphthalimide, and then hydrazinolysis gave the ethylene dihydroxylamine [573].

The nitrate, perchlorate, trinitromethide, and dinitramide salts of this compound have very low melting points, which classifies them as ionic liquids. They are extremely shock sensitive and could not be used as rocket propellants [554]. The most stable ionic liquid in this group was 1,2-ethylene-*N,N'*-bis(hydroxylammonium) mononitrate, with T_m 346–349 K (73–76 °C), T_{dec} 353 K (80 °C), impact sensitivity 94 kg-cm, friction sensitivity 22.8 kg, and showing less impact sensitivity (Olin Matheson-style drop-weight tester with 2-kg mass) than the HMX standard (34 kg cm). Its melting and decomposition temperatures, however, fell short of the desirable values. On the whole, ethylene bis(oxyammonium) salts were extremely sensitive to impact and friction, possessed fairly narrow liquid ranges that were followed by rapid and highly exothermic decompositions, and were unstable (exhibiting visible changes) even when stored under inert atmospheres. See also [556].

6.7 1,3-Propylene-*N,N'*-Dihydroxylamine

1,3-propylene-*N,N'*-dihydroxylamine, 1,3-bis(oxyamine)propane; 1,3-propanediamine, *N,N'*-dihydroxy-; $\text{HO}-\text{NH}-\text{CH}_2-\text{CH}_2-\text{CH}_2-\text{NH}-\text{OH}$, $\text{C}_3\text{H}_{10}\text{N}_2\text{O}_2$, CAS RN [337905-76-7] is a reactant for the preparation of energetic salts.

6.8 *N,N*-Dialkylhydroxylamines

N,N-dimethylhydroxylamine (DMHA) has been used in the separation of uranium from plutonium and neptunium in the reprocessing of spent fuel rods from nuclear power plants. *N,N*-dimethylhydroxylamine has a melting point of 290.7 K (17.6 °C), a boiling point of 373.7 K (100.6 °C), a heat of evaporation of 40.4 kJ/mol (9.670 kcal/mol), and a Trouton constant of 25.9 [538]. The molecular structure, bond lengths, bond angles, electron density, and lone-electron pair interactions of *N,N*-dimethylhydroxylamine have been computed in comparison to other hydroxylamine derivatives [574].

N,N-diethylhydroxylamine in the form of its nitrate salt has been used in HAN-based liquid gun propellants (*Encyclopedia of Monopropellants*, chapter “Hydroxylammonium Nitrate-Based Monopropellants”). The enthalpy of formation of *N,N*-diethylhydroxylamine is -174.8 ± 7 kJ/mol in the liquid state and -121.8 ± 7 kJ/mol in the vapor state.

Mixed Nitric Acid

Nitric Acids

Although chemically speaking there is only one nitric acid with the formula HNO_3 , we have subdivided this chapter into three subchapters in *Encyclopedia of Oxidizers*, dealing with four technical grades of nitric acids of different chemical composition: **white fuming nitric acid** (WFNA), **red fuming nitric acid** (RFNA), and **mixed acid** (MA). There are two variants of RFNA, **inhibited red fuming nitric acid** (IRFNA) and **high-density acid** (HDA).

1 Mixed Acid

The addition of concentrated sulfuric acid or its anhydride to nitric acid (WFNA) shortens the ignition delay with various organic amines. This mixture is called mixed acid, MA. It may also be called mixed nitric acid. Typical MAs contain 88% WFNA and about 12% fuming sulfuric acid (oleum). Organic preparative chemistry has used the addition of sulfuric acid to nitric acid as a means to introduce the nitro or nitrate group into organic compounds for several centuries. This used to be called nitrating acid. Both the improved ignition delay and the increased yield of nitro compounds in organic syntheses are caused by the formation of nitronium ions NO_2^+ in mixtures.

MA is a mixture of about 88 mass-% WFNA and 12 mass-% fuming sulfuric acid with an SO_3 content of 20 mass-%. Fuming sulfuric acid is often described by its traditional name, oleum. The composition of MA is similar but different from nitric acid/sulfuric acid mixtures used in preparative organic chemistry for the nitration of aromatic compounds or alkanols to produce nitro and nitrate ester compounds.

Though MA has no advantages over WFNA or RFNA as far as specific impulse (Isp) performance is concerned, the opposite may be true. MAs were used during World War II because the addition of oleum enhanced the hypergolic ignition of WFNA/hypergolic fuel mixtures with aromatic amines, vinyl ethers, and TONKA amines. Similar mixtures were prepared from nitric acid with perchloric acid replacing some or all of the sulfuric acid, but they have not found flight applications [1].

1.1 Physical Properties of Mixed Acid

The physical properties listed here are of interest for the use of MA as a nitrating acid (still widely used in production of nitrated explosives and nitrocellulose for double-base propellants) and not so much as a rocket propellant oxidizer (because it is no longer used as such).

1.1.1 Freezing Point of Mixed Acid

The freezing points and heat of mixing in the ternary system $\text{HNO}_3/\text{H}_2\text{SO}_4/\text{H}_2\text{O}$ were examined over a wide range of compositions [2]. The freezing point of MA is only 10 °C lower than that of pure nitric acid. Mixing nitric acid and sulfuric acid or even nitric acid and oleum will result in the dehydration of nitric acid, with partial conversion to its anhydride, dinitrogen pentoxide.

1.1.2 Vapor Pressure of Mixed Acid

The vapor pressure of MA is only slightly lower than that of WFNA.

1.1.3 Thermodynamic Properties of Mixed Acid

Mixing WFNA and concentrated sulfuric acid or oleum is an exothermic process. The enthalpies of this mixing process can be read from a nomogram [3].

When preparing MA from concentrated nitric acid and concentrated sulfuric acid or even oleum with an excess of free SO_3 , the mixing heat is exothermic. The integral heats of solutions of HNO_3 in three different grades of H_2SO_4 (different levels of free SO_3 or H_2O) were measured calorimetrically at 298 K, but only for low initial HNO_3 concentrations [4–6]. One of the species formed in MA is $\text{NO}_2^+ \text{HSO}_4^-$. In oleum containing 2.58–4.93% of free SO_3 and with HNO_3 concentrations of 0.1 mol/L, the heat of solution value was $-85.4 \pm 0.8 \text{ kJ/mol}$ ($-20.42 \pm 0.2 \text{ kcal/mol}$).

1.2 Chemical Properties of Mixed Acid

MA does not have a higher specific impulse than WFNA, but the density-specific impulse may be improved slightly due to the higher density of sulfuric acid.

The main reason for the introduction of MA during World War II was that prior to the invention of alkylhydrazines, the ignition delays with various organic amines (aniline, xylidine, triethylamine) could be improved by the addition of sulfuric acid to nitric acid.

The early versions of the Agena upper stage used MA with unsymmetrical dimethylhydrazine (UDMH). MA was used in the early Agena upper stages, but MA is no longer used in the United States.

1.2.1 Analysis Methods for Mixed Acid

The purpose of analyzing MA is to verify the H_2SO_4^- , HNO_3^- , H_2O^- , NOHSO_3^- , and NO_2^- content of a mixture. Several different analysis methods are described in the literature [7, 8].

Extended storage of MA can result in the precipitation of insoluble corrosion products (metal sulfates and metal nitrates), which can clog filters and injector orifices [9].

The sludge must be filtered before conducting an analysis of the liquid, and the precipitate must be analyzed separately.

1.3 Materials of Construction for Mixed Acid

Basically, the same construction materials that are used for WFNA or RFNA can also be used for MA [10].

2 Other Mixtures with Nitric Acid

Attempts were made to lower both the freezing point and the vapor pressure of WFNA by adding other chemicals (other than water or dinitrogen tetroxide). These additives should not worsen the rocket performance of nitric acid as an oxidizer. The additives in this category are mostly nitrates, i.e., salts of nitric acid with various metals or organic bases.

2.1 Solutions of Nitrates in Nitric Acid

2.1.1 Ammonium Nitrate Solutions in Nitric Acid

Solutions of ammonium nitrate in diluted nitric acid have been proposed as high-density oxidizers [11]. They are less corrosive than WFNA or RFNA, which they were intended to replace.

2.1.1.1 Density of Solutions of Ammonium Nitrate in Nitric Acid

The densities of solutions of ammonium nitrate in nitric acid were measured for a wide range of compositions and over two temperature ranges from about 278 to 298 K (5 to 25 °C) and from 269 to 248 K (−4 to −25 °C) in comparison with the densities of solutions of tetramethylammonium nitrate [11–13]. The partial molar volumes of both solutes went through a minimum near 1-molal concentrations. Density-temperature data were obtained for each solute up to concentrations of about 22 mass-%. The density of nitric acid increases with the addition of ammonium nitrate and decreases with the addition of tetramethylammonium nitrate. The data were fitted to straight lines in the form of the equation

$$\rho = \rho_0 - \alpha t$$

where ρ is the density at temperature t in g/cm³, ρ_0 is the density at 0 °C, α is the slope (density coefficient) of the linear function, and t is the temperature in °C. The results are summarized in Table 1 and illustrated in Figure 1.

Table 1: Density coefficients of solutions of ammonium nitrate in nitric acid.

Molality	ρ_0 , g/cm ³	– (negative) α
Ammonium nitrate/nitric acid ratio		
0.02754	1.5491	0.001766
0.05778	1.5500	0.001782
0.2759	1.5511	0.001716
0.5145	1.5548	0.001642
0.8484	1.5625	0.001553
1.125	1.5699	0.001502
1.416	1.5751	0.001443
1.721	1.5795	0.001408
1.876	1.5825	0.001386
2.260	1.5874	0.001344
2.695	1.5922	0.001309
3.331	1.5969	0.001235

Data source: [12]

Figure 1: Density of ammonium nitrate solutions in nitric acid at 273 K. (Reproduced and modified from [12].)

2.1.2 Alkylammonium Nitrate Solutions in Nitric Acid

Alkylammonium nitrate solutions in nitric acid were studied mostly as monopropellants, not so much as methods to lower the freezing point or vapor pressure of WFNA as an oxidizer. Monopropellants made of alkylammonium nitrate solutions in nitric acid were called “CAVEA”.

Figure 2: Comparison of freezing point depression in nitric acid caused by ammonium nitrate or tetramethylammonium nitrate. (Reproduced and modified from [13].)

2.1.2.1 Freezing Points of Alkylammonium Nitrate Solutions in Nitric Acid

On a molar concentration scale, tetramethylammonium nitrate is a more effective freezing point depressant than ammonium nitrate, as shown by a comparison of Figures 1 and 2.

The phase diagram of tetramethylammonium nitrate $[(\text{CH}_3)_4\text{N}]\text{NO}_3$ solutions in nitric acid was measured over a temperature range from 199 to 325 K (-74 to $+52^\circ\text{C}$), covering a range of salt concentrations up to about 50 mass-% [14, 15]. The results are illustrated in Figure 3.

The compositions at the two shallow maxima (shoulders) correspond closely to acid:salt mol ratios of 6:1 and 3:1. Such 6:1 and 3:1 complexes represent a much higher degree of solvation than the 2:1 complexes reported for NO_2 , KNO_3 , and NH_4NO_3 with nitric acid. This is because the tetraalkylammonium ion is a larger ion than K^+ or NH_4^+ ions.

Such solutions of organic amine nitrates in nitric acid are not only usable as oxidizers but may also react as monopropellants (“Cavea” propellants, see *Encyclopedia of Monopropellants*, in the chapter “Nitric Acid or Perchloric Acid-Based Monopropellants”).

2.1.2.2 Densities of Alkylammonium Nitrate Solutions in Nitric Acid

The densities of solutions of tetramethylammonium nitrate in nitric acid were measured for a wide range of compositions and over two temperature ranges from about 278 to 298 K (5 to 25 °C) and from 269 to 248 K (−4 to −25 °C) in comparison to the density of solutions of ammonium nitrate [12]. The partial molar volumes of both solutes went through a minimum near 1-molal concentrations. Density-temperature data were obtained for each solute up to concentrations of about 22 mass-%. The density of nitric acid increases with the addition of ammonium nitrate and decreases with the addition of tetramethylammonium nitrate. The data were fitted to straight lines in the form of the equation

$$\rho = \rho_0 - \alpha t$$

where ρ is the density at temperature t in g/cm^3 , ρ_0 is the density at 0 °C, α is the slope (density coefficient) of the linear function, and t is the temperature in °C. The results are summarized in Table 2 and illustrated in Figure 4.

Data source: [12]

2.1.3 Alkali Metal Nitrate Solutions in Nitric Acid

NaNO_3 and KNO_3 dissolve in 100% HNO_3 with the formation of ions, which is shown by the Raman spectrum. The heat effect is 4184 J (1000 cal) evolved per mol of salt dissolved in a large excess of HNO_3 . The vapor pressure of the solution decreased rapidly with increasing salt concentration [16]. This indicates complex formation between the HNO_3 and NO_3^- . In 80% aqueous HNO_3 the degree of ionization is approximately 2%, and the HNO_3 molecules are in large part hydrated. The vapor pressure of water from this solution is only 266 Pa (2 mm Hg) at 303 K (30 °C). The addition of NaNO_3 or KNO_3 to this solution decreased the HNO_3 vapor pressure and increased the water vapor pressure. This indicated that NO_3^- is a stronger base than water. When a mol of water was added to a large excess of HNO_3 of varying concentrations, the heat evolved increased up to a sharp maximum of approx. 16.7 kJ (4 kcal) for 97% HNO_3 and then decreased very rapidly.

In the IR spectrum, a band at 3400 cm^{-1} characteristic of pure HNO_3 disappeared when the composition was $1\text{ KNO}_3 + 2\text{ HNO}_3$ [17]. At the same time, three new bands appeared at 3150, 2950, and 2700 cm^{-1} .

2.2 Mixtures of Nitric Acid with Other Oxidizers

2.2.1 Mixtures of Nitric Acid and Dinitrogen Pentoxide

Mixtures of nitric acid and dinitrogen pentoxide were investigated extensively as an environmentally more friendly nitrating acid, replacing $\text{HNO}_3/\text{H}_2\text{SO}_4$ nitrating acid

Figure 4: Density of solutions of tetramethylammonium nitrate in nitric acid. (Reproduced and modified from [12].)

and avoiding some of the problems with the disposal of spent nitrating acids in the production of organic nitro compounds, predominantly explosives and toluene diisocyanate precursors. In addition, mixtures of nitric acid and dinitrogen pentoxide would make a good rocket propellant, but only limited testing has been done with this oxidizer so far. The properties of dinitrogen pentoxide are described in *Encyclopedia of Oxidizers*, in the chapter “Dinitrogen Pentoxide.”

The vapor-pressure curve for mixtures of N_2O_5 and HNO_3 at 273 K (0 °C) showed additive behavior, and total pressure equaled the sum of the component vapor pressures [18].

N_2O_5 is best made through the electrolysis of WFNA, but the interim product that is retrieved from the anode space of a diaphragm cell consists of HNO_3 , N_2O_5 , and N_2O_4 . One method of obtaining pure N_2O_5 from this mixture is by extraction with N_2O_4 , in which it is soluble. The phase diagram of the ternary system $\text{HNO}_3/\text{N}_2\text{O}_5/\text{N}_2\text{O}_4$ was investigated by the cloud point method at four different temperatures in support of pure N_2O_5 production [19]. The triangular diagram (Figure 5) can be subdivided into

Figure 5: Phase diagram of $\text{HNO}_3/\text{N}_2\text{O}_5/\text{N}_2\text{O}_4$ system. (Reprinted and modified from [19] with permission from © 2009 American Chemical Society; permission conveyed through RightsLink.)

four phase zones: **(1)** the $\text{N}_2\text{O}_5(\text{S}) + \text{HNO}_3(\text{L}) + \text{N}_2\text{O}_4(\text{L})$ region, **(2)** the $\text{HNO}_3(\text{L})$ region, **(3)** the $\text{HNO}_3(\text{L}) + \text{N}_2\text{O}_4(\text{L})$ region, and **(4)** the $\text{N}_2\text{O}_4(\text{L})$ region. The intersection of the liquid-solid lines and liquid-liquid lines constituted the critical points. At these points, the mass fraction of N_2O_5 was 24.74, 26.57, 24.62, and 19.24% at 258.2, 265.2, 273.2, and 281.2 K, respectively. With an increase in temperature, the two-phase region shrank, and the solubilities of dinitrogen pentoxide in dinitrogen tetroxide and nitric acid, dinitrogen tetroxide in nitric acid, and nitric acid in dinitrogen tetroxide increased correspondingly.

2.2.2 Mixtures of Nitric Acid and Hydrogen Peroxide

Peroxynitric acid, HOONO_2 , plays an important role in atmospheric chemistry in polluted atmospheres, but it is very unstable and not suitable as a rocket propellant. Hundreds of publications deal with the decomposition, mostly by photolysis, of peroxynitric acid, but very few describe how the material can be made in the laboratory. In the stratosphere it forms by recombination of $\text{HOO}^\bullet$ and $^\bullet\text{NO}_2$ free radicals.

Attempts to prepare pure HNO_4 were unsuccessful. Dilute reaction mixtures of HNO_4 were prepared by reacting 50% H_2O_2 with 100% HNO_3 or with N_2O_3 , but the use of 100% H_2O_2 always led to explosions [20]. The highest concentration of HNO_4 in aqueous solutions reached was about 7%. Attempts to prepare salts of HNO_4 were unsuccessful.

2.2.3 Mixtures of Nitric Acid and Perchloric Acid

Low-freezing-point mixtures were obtained by the addition of perchloric acid to nitric acid [1].

Nitrate Esters

1 Alkyl Nitrates

A parallel chapter of *Encyclopedia of Oxidizers* dealt with nitro compounds, which should not be confused with alkyl nitrates. This section and the next several sections deal with alkyl nitrates, which are the esters of nitric acid. This group of compounds is occasionally also referred to as “nitrate esters”, a term that is less specific because it might also include aromatic and heterocyclic rings with nitrato groups attached. The —O—NO_2 nitrate group attached to an organic skeleton is sometimes also called a nitroxy or nitroxyl or nitrato group. Occasionally the R—O—NO_2 compounds have been called “nitro ethers” because there is an oxygen in the middle, but that is a very uncommon designation. The “ether” designation should be reserved for the R—O—R type of compounds.

The current chapter deals mostly with liquid alkyl nitrates. Some solid nitrate esters, such as cellulose nitrate (nitrocellulose) will be included in future chapters on energetic materials in solid propellants. In alkyl nitrates, there may be one or more nitrato groups —O—NO_2 attached to a carbon atom or carbon skeleton. The number of nitrato groups that can be attached is limited by the number of hydrogen atoms that can be replaced by steric hindrance and by the degrading thermal stability of polynitrato molecules with an increasing number of nitroxy groups in the molecule.

The following introductory sections deal with alkyl nitrates as a group and compare their properties. This is followed by sections on specific alkyl nitrates of interest as rocket propellants.

1.1 Preparation of Alkyl Esters of Nitric Acid (Alkyl Nitrates)

Preparation of alkyl nitrates is fairly straightforward by the reaction of alcohols or polyols with nitrating acid (a mixture of anhydrous nitric acid and concentrated sulfuric acid)

The sulfuric acid serves to increase the concentration of nitronium ions and to absorb the water formed in the reaction, thereby shifting the equilibrium toward the right in the direction of ester formation. Because mixtures of alcohols and nitric acid are potentially explosive and may autoignite (even before they start reacting to form alkyl nitrates), the production of alkyl nitrates requires special safety precautions. This is particularly true of the large-scale production of propanetriol trinitrate, glycerol trinitrate (GTN), also erroneously called **nitroglycerin** (NG). Some alkanols can be nitrated by reaction with anhydrous nitric acid alone in the absence of sulfuric acid, making

the product recovery and cleanup a lot easier. Tertiary butyl nitrate can be made in 60% yield by the addition of >98% nitric acid to a cold (243 K = -30°C) solution of the alcohol in methylene chloride.

An excellent summary of the chemistry of alkyl nitrates is Chap. 3 in the book by Agrawal and Hodgson, *Synthetic Routes to Nitrate Esters*, pp. 85–123 [1]. It lists a wide array of methods for the preparation of alkyl nitrate esters. The most common is the O-nitration of alcohols with nitric acid and sulfuric acid. The presence of nitrous acid during the preparation of alkyl nitrates is highly undesirable because the contaminants jeopardize the thermal stability of the nitrate esters. Unwanted nitrite ester formation can be avoided by adding a small amount of urea to the nitrating batch that acts as a nitrite and NO_x scavenger. Methylene chloride is often used as a process solvent for polyol nitrations to allow better temperature control and avoid runaway reactions. Another common nitrating agent is fuming nitric acid in acetic acid anhydride (which is a potentially explosive mixture even before adding the reactant to be nitrated). Dinitrogen tetroxide and dinitrogen pentoxide also have been used as the nitrating agents for the preparation of alkyl nitrates. Nitration is a fundamental chemical process by which less reactive hydrocarbons or alkanols are converted to energetic compounds. Nitration is an important chemical reaction not only for production of rocket propellants and explosives, but also for the chemical process industry in general, producing many intermediates that eventually are converted to dyes, pharmaceuticals, polymers, or pesticides. There are several summary books on the kinetics and industrial applications of nitration reactions [2–5].

The addition of nitric acid to alkenes also leads to the formation of nitrate esters. Isobutylene reacts with fuming nitric acid to form *tert*-butyl nitrate. Other reaction products of alkenes with nitric acid are 2-nitroalkyl nitrates, *vic* dinitrate esters, or nitroalkenes. Metathetical reactions between alkyl halogenides (bromides and iodides) and silver nitrate, preferably in acetonitrile as the solvent, lead to alkyl nitrates with the precipitation of insoluble silver halogenide. Other methods of synthesis of nitrate esters are reviewed in [6]. The synthesis of unsaturated nitrate esters and dinitrate esters in a single step by the use of NO_2BF_4 in diethyl ether at 195 K (-78°C) is a nitration route relatively free from side reactions [7].

The 1963 Proceedings of the International Symposium on Nitro Compounds contains many contributions to the synthesis and applications of alkyl nitrates and nitro compounds [8].

1.2 Natural Occurrence of Alkyl Nitrates

With various alkanes and alkenes floating around in the atmosphere, in particular in the vicinity of petroleum recovery and refining operations, and with NO_2 , ozone, and HNO_3 present in the upper layers of the atmosphere, traces of various alkyl nitrates and alkyl peroxy nitrates are formed and can be detected in the atmosphere and in the

oceans [9]. Alkyl nitrates and alkyl peroxy nitrates participate in the nitrogen cycle in the atmosphere, and as much as 10% of all NO_x may be in the form of alkyl nitrates. Alkyl nitrates form in the atmosphere primarily as a result of the reaction between $\text{RO}^\bullet$ and NO , which competes with the oxidation of NO to NO_2 . In the atmosphere, once formed, alkyl nitrates are photolyzed by sunlight and establish a dynamic equilibrium concentration between the rate of formation and the rate of destruction.

1.3 Properties of Alkyl Nitrates

The lower alkyl nitrates are colorless, low-viscosity liquids whose boiling point is slightly higher than that of the corresponding alcohols. They possess pleasant, sweetish odors, some quite similar to those of the parent alcohols. The nitrates are somewhat denser than the alcohols and have slightly higher refractive indices. Nitrate esters are quite insoluble in water but are miscible with alcohols and ethers.

Summaries of the properties of alkyl nitrates are published in a very useful book on nitrate esters [10].

1.3.1 Mechanical Physical Properties of Alkyl Esters of Nitric Acid (Alkyl Nitrates)

Physical properties of alkyl nitrates are summarized in Table 1.

Table 1: Physical properties of alkyl mononitrates.

Compound	Boiling point		Density	Refractive index
	K	°C	g/cm^3	n_{20}^D
Methyl nitrate	337.7	64.6	1.205	1.3748
Ethyl nitrate	360.8	87.7	1.12	1.3857
<i>n</i> -Propyl nitrate	383	110	1.06	1.3980
<i>iso</i> -Propyl nitrate	375	102	1.05	1.3913
<i>n</i> -Butyl nitrate	406	133	1.03	1.4069
<i>iso</i> -Butyl nitrate	396	123	1.02	1.4026

Data source: [11]

1.3.1.1 Melting Points and Boiling Points of Alkyl Nitrates

Melting points and boiling points of lower alkyl mononitrates are summarized in Table 2.

Table 2: Physical properties of several alkyl nitrates.

Compound	Melting point		Boiling point*	
	K	°C	K	°C
Methyl nitrate	191	−82	338	65
Ethyl nitrate	179	−94	361	88
<i>n</i> -Propyl nitrate	—	—	384	111
<i>iso</i> -Propyl nitrate	191	−82	375	102
<i>n</i> -Butyl nitrate	370	97	409	136
<i>sec</i> -Butyl nitrate	—	—	397	124
<i>iso</i> -Butyl nitrate	—	—	396	123
<i>tert</i> -Butyl nitrate	—	—	294 (0.6 kPa)	21 (5 mm Hg)
Ethylene glycol mononitrate	<253	<−20	364 (2.7 kPa)	91 (20 mm Hg)
Ethylene glycol dinitrate	250.2	−22.8	472 dec.	199 dec.
1-Glyceryl nitrate	327	54	428	155
2-Glyceryl nitrate	331	58	428	155
1,2-Propylene glycol dinitrate	231	−42	365 (1.3 kPa)	92 (10 mm Hg)
1,3-Propylene glycol dinitrate	235	−38	381 (1.3 kPa)	108 (10 mm Hg)
1,2-Glyceryl dinitrate	—	—	419 (2 kPa)	146 (15 mm Hg)
1,3-Glyceryl dinitrate	299	26	419 (2 kPa)	146 (15 mm Hg)
Glycerol trinitrate	286.6	13.5	418 dec.	145 dec.

* Unless otherwise noted, boiling point data are at atmospheric pressure.

1.3.1.2 Vapor Pressures of Alkyl Nitrates

The vapor pressures of alkyl mononitrates can be calculated from the Antoine equation

$$\log p = A - B/(t + D)$$

where p is the decadic logarithm of the vapor pressure in mm Hg, t is the temperature in °C, and A, B, and D are constants. The constants of the Antoine equations that best fit all the available vapor-pressure and normal-boiling-point (NBP) data are listed in Table 3.

Table 3: Antoine equation constants for vapor pressure of alkyl nitrates.

Compound	A	B	D
Ethyl nitrate	7.146	1329	224.0
<i>n</i> -Propyl nitrate	7.246	1444	220.8
<i>iso</i> -Propyl nitrate	7.303	1467	227.5
<i>n</i> -Butyl nitrate	7.607	1742	236.6
<i>iso</i> -Butyl nitrate	7.424	1697	228.6

Data source: [11]

Methyl nitrate was not included in the above table. For methyl nitrate the alternative equation

$$\log p = 26.6767 - 6.3431 \log T - 2620.1139/T$$

has been fitted successfully to the experimental data, where p is the vapor pressure in mm Hg and T is the temperature in kelvin.

1.3.1.3 Physical Properties of Aliphatic Compounds with Two or More Nitroxy Groups

Table 4 is a summary of freezing or melting points and heat of fusion data of aliphatic compounds with two or three nitroxy groups in the molecule. The 1,2,5-trinitroxypentane could not be made to freeze.

Table 4: Freezing or melting points and heat of fusion data of aliphatic compounds with two or three nitroxy groups in molecule.

Compound	Freezing/melting point		Nitrogen content	Heat of fusion			
	K	°C		J/g	cal/g	kJ/mol	kcal/mol
1,3-Dinitroxypentane	243.61	-29.49	16.87	—	—	—	—
1,2,3-Trinitroxypentane (mixed acid nitration)	285.93	12.83	18.51	105	25	23.8	5.68
1,2,3-Trinitroxypentane (straight HNO ₃ nitration)	285.96	12.86	18.51	118	28.1	26.6	6.36
1,3-Dinitroxybutane	285.4	12.3	15.55	93	22.2	16.7	4
1,4-Dinitroxybutane	253.32	-19.78	15.55	148	35.4	26.7	6.38
1,2,4-Trinitroxybutane	261.76	-11.34	17.43	—	—	—	—
1,5-Dinitroxypentane	256.51	-16.59	14.43	80	19.1	15.5	3.7
2,4-Dinitroxypentane	254.62	-18.48	14.43	125	29.8	24.2	5.79
2,5-Dinitroxyhexane	323.47	50.37	13.46	265	63.4	55.2	13.2

Data source: [12]

A method has been developed to predict the melting/freezing points of aliphatic nitrate ester compounds from the molecular mass and molecular structure [13]. The list of examples where predicted freezing/melting points were compared to measured data included nine alkyl nitrates. The average deviation of predicted temperature from measured temperatures was 5.4%. See also [14]. These methods are based on the elemental composition of energetic compounds and the contributions of some specific polar groups/structural moieties as additive and non-additive functions, respectively.

Table 5 is a summary of vapor pressure and heat of evaporation data of aliphatic compounds with two or three nitroxy groups in the molecule.

Table 5: Vapor pressure and heat of evaporation of aliphatic dinitroxy and trinitroxy compounds.

Compound	Vapor pressure, Pa			Vapor pressure, $\mu\text{m Hg}$			Heat of evaporation	
	Temperature, K			Temperature, $^{\circ}\text{C}$			kJ/mol	kcal/mol
	293	303	313	20	30	40		
1,3-Dinitroxypropane	2.26	5.4	15.4	17	41	116	75 ± 5	17.9 ± 1.1
1,2,3-Trinitroxypropane I	0.03	0.11	0.4	0.21	0.82	3.2	105 ± 6	25.1 ± 1.4
1,2,3-Trinitroxypropane II	0.03	0.15	0.5	0.2	1.1	3.5	109 ± 11	26 ± 2.7
1,3-Dinitroxybutane	2.9	6.8	18.9	22	51	142	72 ± 7	17.2 ± 1.7
1,4-Dinitroxybutane	1.21	2.7	5.4	9.1	20	41	57 ± 0.8	13.7 ± 0.2
1,2,4-Trinitroxybutane	0.15	0.33	0.7	1.1	2.5	5.3	60 ± 11	14.4 ± 2.7
1,5-Dinitroxy pentane	0.62	1.8	4.9	4.7	13.6	36.5	79 ± 6	18.8 ± 1.4

* Heat of evaporation computed by subtracting heat of fusion.

Data source: [12]

Table 6 lists the vapor pressures of GTN in comparison to those of other alkyl polynitrates. Samples of the following esters were prepared in a high state of purity and vapor pressures determined over a temperature range of 288 to 328 K (15 to 55 $^{\circ}\text{C}$): GTN, ethylene glycol dinitrate (EGDN), diethylene glycol dinitrate (DEGDN), propylene glycol dinitrate (PGDN), and trimethylene glycol dinitrate [15]. The data presented in Table 6 are also illustrated in Figure 1.

The vapor pressures of methyl nitrate, ethyl nitrate, *iso*-propyl nitrate (IPN), butyl nitrate, and isoamyl nitrate were measured at 263, 273, and 283 K (−10, 0 and +10 $^{\circ}\text{C}$) by a static method [16].

Table 6: Vapor pressure of GTN and other alkyl polynitrates.

Temperature, K	288	288	298	298	308	308	318	318	328	328
	15	15	25	25	35	35	45	45	55	55
Vapor pressure	Pa	mm Hg	Pa	mm Hg	Pa	mm Hg	Pa	mm Hg	Pa	mm Hg
Glycerol trinitrate	0.17	0.0013	0.24	0.0018	0.61	0.0046	1.72	0.0129	4.8	0.0359
Ethylene glycol dinitrate	3.11	0.0233	9.41	0.0706	29.2	0.2189	59	0.4425	128	0.9619

1.3.1.4 Densities of Alkyl Nitrates

The densities of a few alkyl mononitrates were already presented in Table 1. For some applications of alkyl nitrates, such as in explosives, density is an important performance parameter. The densities of alkyl nitrates can be determined experimentally, and several measured data for individual compounds are listed later on or can be predicted theoretically. One of the first predictive methods was based on the group additivity method [17], comparing predictions for 173 energetic compounds with experimental results.

Correlations to predict crystal density based on two different models were introduced for 82 different energetic compounds, including 9 nitrate esters whose molecules contained functional groups common to CHNO explosives [18–20]. Additional work expanded the list of energetic materials to 172 compounds [21]. Root mean square (RMS) deviations for acyclic and cyclic nitramines were worse than for nitrate esters and nitroaliphatic explosives. This method is a simple procedure for predicting the crystal densities of energetic compounds, and it gave good results compared

to group additivity methods for estimating the density of organic explosives. The predictions are less accurate for liquid alkyl nitrates. See also [22].

1.3.2 Optical Properties of Alkyl Nitrates

1.3.2.1 Infrared Spectra of Alkyl Nitrates

This section contains information on the IR spectra of alkyl nitrates as a group, often providing a discussion of the differences in absorption spectra with increasing length or branching of the alkyl rest. IR spectra of selective alkyl nitrates are in subsequent individual sections on specific alkyl nitrates. IR spectra can be used to identify the type of carbon atom to which the —O—NO_2 group is attached. The spectra of primary, secondary, and tertiary alkyl nitrates are different. If the —O—NO_2 group is close to other bulky groups, the asymmetric and symmetric bands of —O—NO_2 will be blue shifted.

A vibrational analysis of the IR spectra of several alkyl mononitrates was the foundation of an investigation of the applicability of force constants from one alkyl nitrate to another alkyl nitrate [23]. IR spectra and analyses were reported for methyl, ethyl, *n*-propyl, isopropyl, and propylene nitrates.

1.3.2.2 Raman Spectra of Alkyl Nitrates

The Raman spectra of methyl, ethyl, propyl, butyl, amyl, hexyl, or heptyl nitrates were measured and compared to each other [24]. New lines were found, and others were shown to belong together as doublets. The frequency due to the NO_3^- ion did not occur in methanol solutions of methyl nitrate. The frequencies 1295 and 1679 cm^{-1} in 99.8% HNO_3 corresponded to internal vibrations, comparatively little influenced by the alkyl rest R, of the —NO_2 groups, while the frequency 612 cm^{-1} related to the angle subtended by the two oxygen atoms, and it decreased to 570 cm^{-1} when R was larger than methyl. The differences between the corresponding frequencies of the alkyl carbon chain decreased as the length of the chain increased.

The Raman spectra of 8 alkyl nitrates and 24 other explosives were recorded for use in an explosive detection device [25, 26]. The samples were excited with the 1064-nm line from a diode-pumped Nd:YAG laser. The spectra showed the typical bands for the —O—NO_2 nitrate ester group for ν_s at $1300\text{--}1270\text{ cm}^{-1}$ and ν_{as} at $1660\text{--}1610\text{ cm}^{-1}$ (Figure 2). The typical nitrate ester Raman features are as follows:

1. Broad and intense aliphatic CH stretching vibrations
2. Anti-symmetric NO_2 stretching vibration observed as a broad feature in the majority of covalent nitrate spectra between 1670 and 1630 cm^{-1}
3. Symmetric stretching vibration of the nitro groups observed at approximately 1280 cm^{-1} and varies by up to $\pm 14\text{ cm}^{-1}$.
4. Intense broad band observed at approximately 860 cm^{-1} (Figure 2); this band is tentatively assigned to the O—N stretching mode. The measured frequencies are summarized in Table 7.

Table 7: Observed wavenumbers of symmetric and anti-symmetric $\nu(\text{NO}_2)$ Raman band.

Compound	Acronym	Wave number of $\nu_s(\text{NO}_2)$ band cm^{-1}	Wavenumber of $\nu_{as}(\text{NO}_2)$ band cm^{-1}
Glycerol trinitrate	GTN	1294	1656
Pentaerythritol tetranitrate	PETN	1288	1658
Trimethylolethane trinitrate	TMETN	1287	1647
Nitrocellulose	NC	1287	1667
Propylene glycol dinitrate	PGDN	1286	1639
Mononitroglycerol	MNG	1282	1638
Diethylene glycol dinitrate	DEGDN	1281	1636
Triethylene glycol dinitrate	TEGDN	1280	1634

Data source: [26]

**Figure 2:** Raman spectra of PGDN (top) and GTN (bottom). (Republished and modified from [25], with permission of © 1995 Elsevier; Permission conveyed through RightsLink.)

1.3.2.3 NMR Spectra of Alkyl Nitrates

The nuclear magnetic resonance (NMR) spectra of alkyl nitrates are useful to identify explosive residues from accident scenes and to identify contaminants in propellants that may be responsible for the inferior quality of a product. The ^1H NMR spectra of 21 alkyl nitrates and alkylene dinitrates and a few trinitrates were recorded and compared [27]. A complete analysis of the ^1H NMR spectra was not possible because the spectra were more complex than those of the corresponding fluorides, which gave deceptively simple spectra. In others the resolution was not sufficient to allow all the NMR parameters to be evaluated. It would be difficult to use NMR in the analysis of

nitrate ester mixtures. As an example, Figure 3 shows a trace of ethyl nitrate (b) as a contaminant in IPN (a).

Figure 3: NMR spectrum of ethyl nitrate (b) as a contaminant in IPN (a). (Reproduced and modified from [27].)

1.3.3 Molecular Structure of Alkyl Nitrates

The generally recognized structure of the nitrate group $-\text{NO}_3$ in nitrate esters is a symmetrical structure:

The bond lengths and bond angles of nitrate esters are similar to those of nitro compounds. Because nitrate esters are so much more reactive than nitro compounds, it has been speculated that one of the more reactive species in alkyl nitrates might be a hyperoxide group

However, the hyperoxide structure was not found in nitrate esters after multiple chemical structure analysis techniques. The only structure of nitrate esters is

The structure of nitrate esters was further characterized by Raman spectroscopy, IR spectroscopy, electron diffraction, dipole moment, and X-ray diffraction (XRD). The results supported the finding of no hyperoxide structure in nitrate esters.

Three density-functional methods were used to investigate the O—NO₂ bond lengths, frontier orbital energies, and O—NO₂ bond dissociation energies (BDEs) of IPN, *n*-propyl nitrate (NPN), 2-ethylhexyl nitrate (EHN), tetraethylene glycol dinitrate (Tetra-EGDN), and TEGDN [28]. It was found that the O—NO₂ bond lengthens (destabilizes) in the aforementioned order. From the data of frontier orbital energies and energy gaps, the relative thermal stabilities of the five nitrates and their corresponding radicals was estimated, and the predicted BDEs of O—NO₂ bonds in IPN, NPN, EHN, Tetra-EGDN, and TEGDN were 174.5, 176.6, 168.1, 159.3, and 156.1 kJ/mol, respectively. Based on the finding that the results of BDEs were in agreement with experimental results of apparent activation energies from the literature, it was suggested that the experimental thermolysis of these five nitrates is only unimolecular homolytical cleavage of the O—NO₂ bonds.

1.3.4 Thermodynamic Properties of Alkyl Esters of Nitric Acid (Alkyl Nitrates)

The vapor pressures of *n*- and *iso*-propyl and *n*- and *iso*-butyl nitrate were measured from 273 to 344 K (0 to 70 °C), and their NBPs were remeasured [11]. From these numbers accurate values could be derived for the latent heats of evaporation of the nitrates at 298 K (25 °C) and at their boiling points by means of the Clausius-Clapeyron equation. In Table 8 the corrected and the uncorrected latent heats of evaporation of the six alkyl nitrates are listed, for evaporation at 298 K (25 °C), and at the NBPs at atmospheric pressure.

Table 8: Corrected enthalpy of evaporation of alkyl nitrates.

Compound	ΔH_{vap} at 298 K		ΔH_{vap} at NBP		ΔS_{vap}	
	kJ/mol	cal/mol	kJ/mol	cal/mol	J K ⁻¹ mol ⁻¹	cal °C ⁻¹ mol ⁻¹
Methyl nitrate	34.1	8150	31.5	7540	93.3	22.3
Ethyl nitrate	36.3	8670	33.1	7920	91.6	21.9
<i>n</i> -Propyl nitrate	40.6	9700	35.9	8580	93.3	22.3
<i>iso</i> -Propyl nitrate	38.8	9270	34.9	8350	92.9	22.2
<i>n</i> -Butyl nitrate	43.6	10420	39.1	9340	96.7	23.1
<i>iso</i> -Butyl nitrate	42.2	10080	37.3	8920	95.0	22.7

Data source: [11]

All the Trouton constants were about $22.5 \pm 0.5 \text{ cal } ^\circ\text{C}^{-1} \text{ mol}^{-1}$, an indication that no association of molecules took place in the vapor phase. The variation of latent heat with temperature indicated that at room temperature fewer than half the possible vibrational modes are active in gaseous nitrates.

The heats of combustion of liquid ethyl nitrate, NPN, and IPN were measured using a bomb calorimeter of conventional design from which the heats of formation were derived [29]. The results obtained are shown in Table 9. See also [30, 31].

Table 9: Heat of combustion and heat of formation of liquid alkyl nitrates.

Compound	ΔH_c°		ΔH_f°	
	kJ/mol	kcal/mol	kJ/mol	kcal/mol
EtNO ₃	-1311 ± 0.96	-313.39 ± 0.23	-190.4 ± 1.04	-45.51 ± 0.25
<i>n</i> -PrNO ₃	-1966 ± 1.2	-470.00 ± 0.3	-214.5 ± 1.2	-51.27 ± 0.3
<i>iso</i> -PrNO ₃	-1951 ± 1.2	-466.35 ± 0.3	-229.8 ± 1.2	-54.92 ± 0.3

Data source: [29]

1.3.4.1 Computational Prediction of Thermodynamic Properties of Alkyl Nitrates

Heats of formation for several nitramines and alkyl nitrates were calculated with two semiempirical molecular orbital theory methods [32]. Both methods can estimate heats of formation ΔH_f° accurately. By combining heats of evaporation and sublimation obtained by the additivity rule with ΔH_f° in the gas phase obtained by this predictive method, heats of formation ΔH_f° in condensed phases can be estimated accurately enough for energetic accident hazards predictions.

The ideal gas (**not** condensed phase!) thermodynamic properties of 29 nitro and alkyl nitrate compounds, including NPN and GTN, were predicted from spectroscopic data and compared to calorimetric results reported in the literature [33, 34]. The fundamental vibrations, bond lengths, and moments of inertia of all the molecules were calculated using semiempirical methods. The resulting thermodynamic properties were represented in a polynomial form, ready for use in rocket propulsion I_{sp} calculations. The format used was the OLD NASA CEC polynomial format and consisted of two sets of polynomial coefficients for each species. The first set of seven coefficients represented the properties above 1000 K and the second from 200 to 1000 K. Both polynomials gave the same values at 1000 K for the properties. The 15th (last) coefficient represented the enthalpy of formation $\Delta H_f(298)/R$. The results are summarized in Table 10.

Table 10: Ideal gas thermodynamic properties of alkyl nitrate compounds.

Gaseous (vapor) compound name	Formula	ΔH_f^{298} kJ/mol	S^{298} JK ⁻¹ mol ⁻¹	C_p^{300} JK ⁻¹ mol ⁻¹
Methyl nitrate	CH ₃ ONO ₂	-122.01	305.79	76.88
Nitroxymethyl free radical	•CH ₂ ONO ₂	98.95	312.17	77.05
Ethyl nitrate	C ₂ H ₅ ONO ₂	-154.98	928.86	95.54
<i>n</i> -Propyl nitrate	C ₃ H ₇ ONO ₂	-174.05	362.60	123.79

Data source: [34]

The N—O BDEs and the heats of formation of alkyl nitrate and alkyl nitrite compounds in the gas phase at 298 K were theoretically calculated using a density functional theory (DFT) method [35]. The DFT and the *ab initio* method can both yield good results with respect to the experimental heats of formation with a deviation of less than 8.1 kJ/mol (2.0 kcal/mol). As the number of methylene groups increased, the heats of formation of alkyl nitrate and nitrite compounds increased with the number of carbon atoms.

Comparative quantum chemical calculations have been carried out for five nitrate esters: ethyl nitrate, NPN, IPN, EHN, and tetraethylene glycol dinitrate (Tetra-EGDN) [36]. The relative thermal stability ordering of the five nitrates was estimated on the basis of the frontier orbital energy and the energy gap. The heats of formation of the five alkyl nitrates ethyl nitrate, NPN, IPN, EHN, and Tetra-EGDN in the vapor state calculated from isodesmic reactions were -156, -175, -191, -272, and -791 kJ/mol, respectively.

The heats of formation of 24 nitrate esters in the vapor state were computed by quantum chemical calculations and compared to experimental data for only 5 nitrate esters available from the literature [37]. The calculated heats of formation of the five compounds were very close to measured data for ethyl nitrate, NPN, IPN, EGDN, and GTN. The heats of formation of 19 other nitro ester energetic compounds were tabulated. The computed heat of formation decreased when the number of methylene (CH₂) groups increased for normal alkane chain nitrate ester compounds.

The molecular structure and bond energies of aliphatic polynitrates of polyols were studied using a DFT method [38]. The IR spectra of a few samples were measured and used to compute the thermodynamic properties based on the absorption band frequencies and principles of statistic thermodynamics. The reliability of this theoretical method was tested by comparing the theoretical densities with the experimental ones. Detonation properties were predicted using modified Kamlet-Jacobs equations based on the calculated densities and heats of formation. The energetic properties of other polyol nitrates, e.g., xylitol pentanitrate (XPN) or mannitol hexanitrate (MHN), were examined as well.

1.3.4.2 Computational Prediction of Density of Alkyl Nitrates

Correlations to predict densities based on two different models were introduced for 82 different energetic compounds, including nitrate esters and nitroaliphatic compounds whose molecules contained functional groups common to CHNO explosives [18–20]. The RMS deviations for acyclic and cyclic nitramines were worse than for nitrate esters and nitroaliphatic explosives. This method is a simple procedure for calculating the density of energetic compounds and gave good results compared to group additivity methods for estimating the density of organic explosives.

1.4 Chemical Properties of Alkyl Nitrates

1.4.1 Reactions of Alkyl Nitrates

Unwanted reactions of alkyl nitrates during their synthesis may reduce the yield or lead to unwanted byproducts that are difficult to remove and may worsen the sensitivity of the compounds, making them more hazardous.

Controlled reactions of alkyl nitrates that we want to learn more about are the thermal or catalytic decomposition taking place in rocket engines, which will be discussed in *Encyclopedia of Monopropellants*. Alkyl nitrates have been extensively examined as additives to diesel fuels to improve the cetane number and facilitate ignition under arctic conditions. The initial reactions in the decomposition of alkyl nitrates taking place in diesel fuel droplets during the compression stroke are similar to those during startup in a monopropellant rocket engine.

At the end of their useful lifetime, alkyl nitrates may have to be disposed of as part of a demilitarization of outdated weaponry or to clean up a spill. Many different reactions can convert hazardous alkyl nitrates to innocuous products that can be safely burned or landfilled. The disposal of alkyl nitrates is discussed in Section 9.3.1.1.7 and 9.4.6.

The lifetime of alkyl nitrates that exist in the atmosphere either naturally or as the result of anthropogenic pollution is limited by photolysis in bright sunlight. The photolysis of alkyl nitrates is discussed in Section 1.4.3.

All esters are eventually susceptible to hydrolysis, converting them back to alcohols and acids. The hydrolysis of alkyl nitrates is very undesirable and may limit their useful lifetime in moist environments or if they were not perfectly dried following production and prior to sending them into storage. Nitric acid formed during hydrolysis would be very corrosive to shipping containers.

A historical and very detailed summary of the reactions of alkyl nitrate esters is found in [6]. This work contains sections on synthesis, physical properties, chemical reactions, physiological properties, and hazards involved in handling alkyl nitrates, along with 188 literature references to now mostly antiquated earlier publications.

1.4.1.1 Hydrolysis of Alkyl Nitrates

It is surprising that hydrolysis of nitrate esters involves the occurrence of other reactions besides the normal ester hydrolysis to alcohol and nitrate ion or nitric acid. Considerable confusion has existed, especially in the older literature, regarding these side reactions, with some investigators believing that they arise from a subsequent oxidation reduction between the alcohol and nitric acid, while others regarded the side reactions as proceeding simultaneously with, and independently of, the normal hydrolysis reaction. The hydrolysis of nitrate esters may actually take place by a combination of three distinct reactions:

(1) Nucleophilic substitution:

(2) Elimination of β -hydrogen:

(3) Elimination of α -hydrogen:

Reaction (1) predominates in both alkaline and neutral hydrolysis of primary and secondary alkyl nitrate esters. Besides alcohols and nitrate in reversal of the formation reaction, the hydrolysis of alkyl nitrates may create aldehydes, ketones, carboxylic acids, and unsaturated hydrocarbons as byproducts [39, there p. 187–190]. Reactions are sought for the disposal of unwanted alkyl nitrates. In addition to the hydrolysis of alkyl nitrates, reactions with sodium hydrogen sulfide have been extensively investigated.

The hydrolysis of alkyl nitrates precedes several analysis methods. Several hydrolysis methods have been tested to make sure none of the volatile nitrate is lost during the procedure. One of the hydrolysis procedures uses metallic calcium in a solution of potassium methanolate in methanol [40]. Hydrolysis would be a preferred way for the disposal and inerting of alkyl nitrates.

1.4.1.2 Acidity of Alkyl Nitrates

Similar to the acidity of the α -hydrogen in nitroalkanes, the α -hydrogen in alkyl nitrates is acidic and can also form salts. The salts are more sensitive than the parent alkyl nitrate.

1.4.1.3 Alkyl Nitrates as Nitrating Agents

Alkyl nitrates can serve as the source of $-\text{NO}_3$ or $-\text{NO}_2$ in the preparation of other nitrate and nitro compounds. In concentrated sulfuric acid, nitrate esters undergo a complex ionization, yielding nitronium ion NO_2^+ , which is the main nitrating agent.

1.4.2 Thermal Decomposition of Alkyl Nitrates

Alkyl nitrates have good storage stability and can be stored in the dry state for a long time without decomposition; however, some contaminants will decrease storage stability and lower the autodecomposition temperature. Alkyl nitrates, nitramines, and nitro compounds have in common that they possess a $-\text{NO}_2$ group. The thermal stability of these three groups of energetic chemicals differs significantly, depending on how the $-\text{NO}_2$ group is linked to the hydrocarbon skeleton. The best thermal stability

is achieved by direct linkage of the $-\text{NO}_2$ group to a carbon atom. The intermediate $-\text{N}-$ or even $-\text{O}-$ atom will make the chemical more reactive and less stable. On the other hand, thermally less stable compounds are easier to ignite in a monopropellant rocket engine. The thermal stability of alkyl nitrates is inferior to that of nitramines. All alkyl nitrates will autodecompose exothermally above a certain autodecomposition temperature. Compounds that autodecompose below their boiling point at normal pressure must be distilled (with adequate precautions) under reduced pressure. Studies on the inflammation of alkyl nitrate vapors have demonstrated the existence of three modes of thermal decomposition: chemiluminescence, explosion, and decomposition without glow. The luminescent mode, as obtained at low pressures in the case of methyl nitrate, was attributed to the methoxyl radical and, as such, was substantiation of the primary reaction being the fission of the alkoxyl-nitrogen bond.

This chapter is primarily concerned with the decomposition of alkyl nitrates in the absence of additional oxidizers or catalysts. Many studies have looked at vapor decomposition flames and flames stabilized on stationary burners, usually at low pressure or with inert gas diluents, but without the addition of oxygen. However, a few studies have also looked at flames burning in oxidizing environments (ambient air), and we have included these here as well, since they help to understand the monopropellant burning mechanism. Decomposition data on specific alkyl nitrates will be presented in subsequent sections. This section discusses general aspects on the decomposition of alkyl nitrates as a family of compounds, often comparing the properties of different alkyl nitrates that are either structural isomers or homolog, and looking for a correlation between molecular structure and thermal decomposition, in particular trying to find the weakest link in the molecule.

1.4.2.1 Slow Thermal Decomposition of Alkyl Nitrates

The thermal decomposition of four different alkyl nitrates was measured and compared in view of the different structures of these molecules. The four alkyl nitrates tested were IPN, *sec*-butyl nitrate, *n*-butyl nitrate, and ethylene glycol mononitrate (EGMN) [41].

The decomposition of alkyl nitrates often leads to alkyl nitrites, which in turn will decompose on further heating and are much less stable than the nitrates from which they are derived [42]. The alkyl nitrites are also the isomers of the nitro compounds with the same gross chemical formula and were at one time suspected to be intermediates in the decomposition of nitro compounds. One example alkyl nitrite is isopropyl nitrite which will be discussed further down in the chapter on IPN.

The thermal decomposition of ethyl nitrate was already examined by a number of researchers [43, 44], and it was proposed that the first, and rate-determining, step was the reversible loss of NO_2 :

Rates of thermal decomposition and solvent rate effects were measured for a series of nitrate esters. The alkoxy radicals formed by homolysis together with some of their further degradation products have been stabilized by hydrogen donation. Internal and external return of nitrogen dioxide has been demonstrated by solvent cage effects and isotope exchange. Radical stabilizing substituents favor β -scission. Dinitrates in a 1,5 relationship behave as isolated mononitrates. Dinitrates in a 1,3 or 1,4 relationship exhibit intramolecular reactions. Tertiary nitrate esters in diethyl ether undergo elimination rather than homolysis.

Summaries of the reactions in the pyrolysis of alkyl nitrates, alkyl nitrites, and nitro compounds are published in [45] and [46]. The culprit in the autocatalytic acceleration of alkyl nitrate decomposition may not be NO_2 , as was widely assumed, but actually it may be formaldehyde [47].

The thermal decomposition rates were measured and mechanisms proposed for the following primary, secondary, and tertiary mononitrates: *n*-pentyl nitrate, 3-buten-1-yl nitrate, ethyl nitrate, neopentyl nitrate, 2-phenylethyl nitrate, 2-propyl nitrate, cyclohexyl nitrate, 2-methyl-2-propyl nitrate, and 2-methyl-2-butyl nitrate [48]. In addition, the mechanisms of thermolysis of the multiple nitrates 1,4-butanediol dinitrate, 1,5-pentanediol dinitrate, 2,2-dimethyl-1,3-propanediol dinitrate, nitropentaglycerin [1,1,1-tris(hydroxymethyl)ethane trinitrate], and pentaerythritol tetranitrate (PETN) have been studied.

A relationship was found between activation energies E_a of low-temperature non-autocatalyzed thermolysis of nitric acid esters on the one hand and their oxygen balances on the other [49]. By this relationship is evidenced a molecular-structural dependence of values E_a , and at the same time existence is signalized of a direct relationship between the values E_a and the impact sensitivity of nitro esters. Similar relationships exist between other sensitivity parameters and molecular structure of polynitro compounds [50, 51].

The primary processes of nitrate ester thermal decomposition, such as homolytic O—N bond scission, the effect of molecular structure, and the reversible elimination of NO_2 were reviewed in an effort to develop thermally more stable energetic materials [52].

In addition to experimental measurement of the decomposition of alkyl nitrates, computational models for thermal decomposition of organic compounds were developed. Based on an analysis of the experimental data on the mechanisms of thermal decomposition, empirical rules were developed for simulating possible thermal decomposition reactions of the major classes of energetic compounds. The proposed approach made it possible to describe the complete spectrum of reactions occurring in the course of thermal decomposition. The approach was exemplified by the simulation of the thermal decomposition of methyl, ethyl, and isopropyl nitrates [53]. All stages of the mechanisms (some of which have been reported in the literature) were

reproduced, and a number of new decomposition reactions, which had not yet been studied experimentally, were suggested.

Measurements of the rate constants for the thermal, unimolecular decomposition of organic nitrates confirmed that the rate-determining step is the homolytic cleavage of the weak O—N bond to form alkoxy radical and NO₂, but the rate constants reported previously were found to be incorrect [54]. The alkoxy radical and NO₂ engage in secondary reactions that ultimately generate stable products such as carbonyl and nitro compounds. IR and gas chromatography-mass spectrometry (GC/MS) were used to monitor the time-dependent loss of organic nitrates and to characterize the products of the thermal reactions. Past research indicated that oxygen slowed the rate of homolytic O—N bond cleavage to form radicals, but now it was found that the rates are the same in nitrogen as they are in air. Unhindered, linear alkyl nitrates have lower reaction rate constants than sterically hindered organic nitrates. Activation energies were found to be lower for sterically hindered organic nitrates. The steric strain present in the hindered organic nitrates may account for the weaker O—N bonds and faster thermal reaction rates. Reaction rates for thermal decomposition under nitrogen were found to decrease as the viscosity of the solvent increased.

If the influence of chemical structure on the thermal stability of nitric acid esters were fully understood, one could design nitric acid esters with improved thermal stability. In trying to establish a correlation between molecular structure and thermal stability, the thermal stability and decomposition mechanism functions of 10 nitric acid esters, including glycerol trinitrate (NG), PETN, trimethylolethane trinitrate (TMETN), dipentaerythritol hexanitrate (DiPEHN), trimethylolpropane trinitrate (TMPTN), erythritol tetranitrate (ETN), XPN, sorbitol hexanitrate (SHN), MHN, and nitroisobutylglycerol trinitrate (NIBGT) were determined by non-isothermal thermogravimetric analysis (TGA) and differential scanning calorimetry (DSC) [55]. It was found that the mean activation energies for most nitric acid esters were comparable at a constant heating rate (around 145 kJ/mol), indicating that their main decomposition pathways might be the same. Based on the critical temperature of thermal decomposition, the order of molecular stability for nitric esters was MHN XPN TMPTN SHN NIBGT ETN PETN DiPEHN. The introduction of functional groups to the tertiary carbon may increase thermal stability due to an increase of symmetry and rigidity of the molecule. Two types of decomposition kinetic behavior were observed, and most nitrate esters followed typical decomposition kinetics close to the first-order reaction.

The thermal stability of 10 different nitric acid esters was evaluated in an effort to explain the relationship between molecular structure and thermal stability [56]. The thermal stability and decomposition kinetics of 10 nitric acid esters, including NG, PETN, TMETN, TMPTN, XPN, SHN, ETN, mannitol hexanitrate, and NIBGT, were investigated by non-isothermal TGA and DSC. It was shown that the mass loss processes of NG, TMETN, and TMPTN are more dependent on the heating rate, and the simultaneous evaporation makes the initial temperatures for their mass loss lower than those

of the other nitric esters. Based on the correlations among their thermal stability, activation energy, detonation velocity, and heat of combustion, it was concluded that the oxygen coefficient (α) plays a positive role in the decomposition heat release efficiency (η_d) when it is less than one, whereas when the α is greater than or equal to one, the fuel elements, such as C and H contents, would play a decisive role in η_d . It was shown that the order of contribution rate of function groups on the tertiary carbon to the detonation velocity could be $-\text{CH}_3 > -\text{NO}_2 > -\text{C}_2\text{H}_5 > \text{ONO}_2$. The introduction of functional groups to the tertiary carbon facilitates increasing the thermal stability of nitric acid esters due to an increase in symmetry and rigidity of their molecules. The ratio numbers (C_s) of the methylene group ($-\text{CH}_2-$) to tertiary carbon or quaternary carbon will also, to some extent, determine the thermal stability of the nitric acid esters.

1.4.2.2 Rapid Thermal Decomposition of Alkyl Nitrates

T-Jump/Fourier transform infrared (FTIR) and T-jump/Raman spectroscopies were used to analyze the gaseous products from six nitrate esters, which were rapidly heated (2000 °C/s nominal) to preset temperatures in the 523 to 773 K (250 to 500 °C) range while maintaining a pressure of 0.5 MPa (5 atm) Ar [57]. The compounds studied were GTN, PETN, butanetriol trinitrate (BTTN), TMETN, triethyleneglycol dinitrate (TEGDN), and bis(nitratomethyl) oxetane (BNMO). With few exceptions, the oxygen balance of the nitrate esters correlated with the thermal stability of the products, the CO_2/CO ratio, the NO/CO ratio, and the amounts of H_2O and total hydrocarbon liberated. The amounts of NO_2 and CH_2O scaled with the number of $-\text{NO}_2$ groups and $-\text{CH}_2\text{O}-$ units in the parent molecule. The relation between the composition of the parent nitrate ester and the gaseous products from pyrolysis was the most straightforward of the various classes of oxidizing energetic functional groups studied by that group to date. Some degree of evaporation of the undecomposed parent nitrate ester was observed upon flash heating and identified by IR. The IR-active modes of GTN and BTTN in the gaseous phase were assigned by calculation of their frequencies by DFT in the energy-minimized structure. The pyrolysis of alkyl nitrates and alkyl nitrites is described in [58].

1.4.3 Photolysis of Alkyl Nitrates

The photolysis of alkyl nitrates is discussed in this chapter because it is a method for controlled and repeated ignition of a decomposition reaction in rocket engines by laser photolysis. Photolysis determines the rate of decay of spilled propellants in surface waters under the influence of sunlight. UV-photolysis is a useful method for decontaminating wastewaters from propellant production facilities.

The discovery of naturally occurring alkyl nitrates in the atmosphere and in the ocean has prompted a large number of investigations in the photolysis of alkyl nitrates and alkyl nitrites in order to see what equilibrium concentrations one must expect un-

der conditions of sunlight illumination. For the use of alkyl nitrates as rocket propellants, photolysis would only be of interest as a means of ignition in a rocket engine or as a means of wastewater treatment from propellant production plants. The use of alkyl nitrates as rocket propellants does not contribute to atmospheric contamination.

Organic nitrates produced in the atmosphere through photochemical reactions involving hydrocarbons and oxides of nitrogen may constitute a significant fraction of reactive nitrogen oxide NO_x . UV absorption cross sections of methyl, ethyl, 1- and 2-propyl, 1-, 2-, and *tert*-butyl, cyclopentyl nitrate, and (nitrooxy)ethanol were measured to provide estimates of atmospheric removal rates [59]. The spectra were very similar in the range of atmospheric interest (290 nm), and UV absorption cross sections decreased from $\sigma = 10^{-20} \text{ cm}^2 \text{ molecule}^{-1}$ to $10^{-22} \text{ cm}^2 \text{ molecule}^{-1}$ above 330 nm. An increasing trend in σ was observed with length and degree of substitution of the alkyl substituent.

The UV absorption cross sections of methyl, ethyl, and IPN between 233 and 340 nm have been measured using a diode array spectrometer in the temperature range 240–360 K [60]. The absorption cross sections of these alkyl nitrates decreased with increasing wavelength and decreased with decreasing temperature for $\lambda \geq 280 \text{ nm}$. The photodissociation quantum yield for CH_3ONO_2 to produce NO_2 and CH_3O was essentially unity at 248 nm using transient UV absorption methods. Production of O and H atoms in the photodissociation of methyl nitrate at 248 and 308 nm was negligible using resonance fluorescence detection of the atoms. High quantum yields for O atoms were measured following 193-nm photolysis of methyl nitrate. The OH radical was a photoproduct with a very small quantum yield. Using OH rate coefficients, UV absorption cross sections, and photodissociation quantum yields, the first-order rate constants for atmospheric loss of methyl, ethyl, and IPN were calculated. Photolysis was found to be the dominant atmospheric loss process for the three alkyl nitrates.

1.4.4 Analysis of Alkyl Nitrates

Analytical methods for alkyl nitrates are needed for quality control of the propellant ingredients and for monitoring workroom air where personnel may be exposed to physiologically active vapors. Because of the strong effect of alkyl nitrate vapors on blood pressure, air monitoring in the workplace is extremely important. Vaporizing energetic plasticizers are a main aging mechanism, limiting the storage and service life of double-base propellants, and therefore vapor concentrations of plasticizers in propellant or assembled munitions storage areas need to be measured periodically. Another area where sensitive analytical methods are needed is the detection of explosive vapors in aircraft luggage, suspected terrorists, and buried land mines, a category often described as improvised explosive devices (IEDs).

Because of the low thermal stability of nitro and nitrate compounds, the operating temperature of gas liquid chromatography (GLC) columns for the GC analysis of these compounds is limited. Oven temperature, column material, and column length must be chosen to achieve good separation without losing any of the analyte in the process [61]. To prevent accumulation of less volatile compounds on columns, it was recommended to wash columns with acetone after every 50th injection.

GTN, EGDN, and dinitrotoluene can be detected by optoacoustic spectroscopy techniques at 6, 9, and 11 μm [62]. The effect of interference by normal atmospheric pollutants needs to be accounted for, and it was found that of those wavelengths proposed for use, the 9- and 11- μm spectral regions, using a CO_2 laser as radiation source, were the most promising for use in explosive detection.

Nitrate esters show characteristic absorption bands in the IR near 6.1, 7.8, and 11.8 μm , and the last band has been used for the quantitative estimation of ethyl nitrate in complex gaseous mixtures.

The characteristics of the mass spectra of C_1 – C_5 alkyl nitrates (RONO_2) were systematically examined with a proton transfer reaction time-of-flight mass spectrometer operating at different field strengths, E/N , of the drift tube [63]. Although protonated alkyl nitrates were detected for C_1 – C_4 alkyl nitrates, their signal intensities were, at most, only a few percent of the total ion signals. The major product ions were several fragment ions, including NO_2^+ , RO^+ , R^+ , and $\text{ROH}\cdot\text{H}^+$, whose abundances and relative intensities depended on the E/N ratio. The intensity of NO_2^+ ions increased with increasing E/N ratio, whereas the intensities of organic fragments, such as R^+ and RO^+ ions, relative to the total product ions, decreased with increasing E/N ratio. NO_2^+ fragment ions were detected regardless of the speciation of alkyl nitrates, which suggested that the detection of C_1 – C_2 alkyl nitrates by this technique was not selective, but the abundant fragment ion signals of R^+ ions could be useful for the identification of C_3 – C_5 alkyl nitrates.

The structures of organic components in an alkyl nitrate-based propellant (probably similar to Otto Fuel II) were identified by NMR and validated by GC/IR [64]. The organic energetic oxidant (alkylene dinitrate), stabilizer, and phlegmatizer (a sebacate) content of the propellant was quantified. The NMR result was consistent with that obtained by high-performance liquid chromatography (HPLC). The relative standard deviations (RSD) were 0.21% for the organic energetic oxidant, 0.32% for stabilizing agent, and 0.11% for phlegmatizer.

1.5 Handling Safety of Alkyl Nitrates

1.5.1 Toxicity of Alkyl Nitrates

Alkyl nitrates are readily absorbed into the body by inhalation and skin permeation, in addition to accidental ingestion. The most characteristic symptoms of poisoning

by nitrate esters (particularly that due to GTN) are severe headache and a feeling of pressure on the front and back of the head. The dilation of the peripheral blood vessels results in a shift of blood to the splanchnic area and may cause a decreased supply of blood to the brain (despite cerebral vasodilation), resulting in vertigo or fainting. Continued routine exposure to GTN may build up some tolerance against low levels of this compound.

Although alkyl nitrates and alkyl nitrites have several features in common (nitrogen–oxygen grouping, explosiveness, methemoglobin formation), there are significant differences in their toxic effects. Some of their attributes were summarized in a review paper [65]. The esters of nitric and nitrous acids, whose nitrogen is linked to carbon through oxygen, are very similar in their pharmacological effects. Both produce methemoglobinemia and vascular dilatation with hypotension and headache. These effects are transient. None of the compound series has appreciable irritant properties that would warn of their presence in the air in the workplace. Pathological changes occur in animals only after high levels of exposure and are generally non-specific and reversible.

Medicinal uses of alkyl nitrates are for controlled lowering of the blood pressure in hypertensive human patients with high blood pressure. The toxicity of alkyl nitrates is due mainly to their vasodilating effects on the blood and the circulatory system. Alkyl nitrates oxidize hemoglobin to methemoglobin and, by depression of the muscles in the vascular walls, cause a peripheral vasodilation, resulting in lowered systolic blood pressure and increased pulse and respiratory rates. Owing to this vasodilator action, several of the nitrate esters, including amyl nitrate and GTN, are widely used therapeutically for the relief of high blood pressure [66].

1.5.2 Impact Sensitivity of Alkyl Nitrates

GTN is notoriously sensitive to impact and other stimuli. Many industrial accidents have been caused by the impact sensitivity of alkyl nitrates. A method for predicting the impact sensitivity of alkyl nitrates was based on some structural parameters of $C_aH_bN_cO_d$ explosives [67]. Three essential parameters would be needed in this scheme. The results were compared with experimental data and some empirical correlations. Predicted impact sensitivities for 58 explosives had a RMS of deviation from experiment of 27 cm, which was considered good agreement with respect to less accurate values obtained with previous empirical models.

Drop weight impact sensitivities of 58 liquid explosives and melts of high explosives were summarized in [68]. Compounds that were solids at room temperature were heated to just above their melting points. That publication contained data on 12 alkyl nitrate esters, 8 azidonitro compounds, 5 fluoronitro compounds, and 14 nitramines. The data for individual alkyl nitrates were extracted from that paper and inserted in the hazard property tables of individual compounds (Table 11). The compound numbers in the first column of the table are the same as those used in Figure 4. As shown

Table 11: Physical properties and impact sensitivities of alkyl nitrates.

No.	Compound	H50, cm	T, K	T, °C	ΔH_f° , kJ/mol	ΔH_f° , kcal/mol	ρ , g/cm ³	$Q_{\max}$, kcal/g	$\rho Q_{\max}$, kcal/cm ³
1	C(CH ₂ ONO ₂) ₆	2.7	415	142	-558	-133.3	1.6	1.633	2.61

in Figure 4, a linear correlation between impact sensitivity and their maximum volumetric heats of explosion $\rho Q_{\max}$ could be established, similar to one already shown for nitroalkanes in section “Nitroaliphatic Compounds”, see also [69].

Figure 4: Correlation between the sensitivity of nitrates not containing azide and nitramine groups and their maximum volumetric heats of explosion. (Republished and modified from [68], with permission of © 2010 Springer Nature BV; permission conveyed through Copyright Clearance Center Inc.)

1.6 Detonation Performance of Alkyl Nitrates

Many alkyl nitrates are used as explosives instead of rocket propellants [70]. Detonability of alkyl nitrates intended as rocket propellants is more of a disadvantage, and often desensitizing (phlegmatizing) additives are required before alkyl nitrates can be used as rocket propellants, gas generants, torpedo propellants, or liquid gun propellants. The boosted detonation properties of some alkyl nitrates and alkyl nitrites with a charge diameter of 10 mm in steel tubes are summarized in Table 12.

Table 12: Detonation properties of alkyl nitrates and alkyl nitrites.

Compound	Density	Heat of explosion		Detonation velocity
	g/cm ³	kJ/kg	kcal/kg	km/s
Ethylene glycol dinitrite	1.22	5188	1240	6.45–6.50
1,4-Butylene glycol dinitrite	1.17	3598	860	5.19–5.21
2,3-Butylene glycol dinitrite	1.07	3598	860	—
Ethyl nitrate	0.90	2887	690	4.2–4.5
Nitroethane	1.05	3012	720	—
1,4-Butylene glycol dinitrate	1.315	4519	1080	6.25
2,3-Butylene glycol dinitrate	1.30	4519	1080	6.0–6.19

1.7 Applications of Alkyl Nitrates

The list of industrial applications of alkyl nitrates is very long, too long to include in this book. We list here only a few summaries of the uses of alkyl nitrates as energetic materials in propellants and explosives.

A recent book on liquid explosives contains a chapter on the properties and applications of alkyl nitrates as liquid explosives [70]. Some of this information is also useful in evaluating alkyl nitrates as rocket propellants.

The following sections discuss properties and applications of individual alkyl nitrates in detail, starting with mononitrates and then moving on to compounds with more than one nitrate (nitroxy) group in the molecule.

2 Methyl Nitrate

Methyl nitrate, H_3CONO_2 , CH_3NO_3 , $M = 77.0394 \text{ g/mol}$, CAS RN [598-58-3], is an unwanted byproduct in the synthesis of RDX and HMX, and it must be continuously removed during the process. There are few other good uses for this waste material. Theoretically, it could be used as a monopropellant, but it may be too sensitive for that purpose.

Methyl nitrate can be prepared by dissolving methanol in sulfuric acid and slowly adding this solution to a mixture of sulfuric acid and nitric acid with some urea added to prevent formation of nitrites. Both batch and continuous methods were reported to give yields up to 90% [72]. Another synthesis method obtains the product as a 60% solution in methanol, thereby preventing explosions during the nitration.

Methyl nitrate is too sensitive to be used as a rocket propellant by itself and without a diluent. It is mostly used as a simple model substance to study the kinetics of de-

composition in comparison to reactions of higher, more complex alkyl nitrates. Methyl nitrate can be used as a mild nitrating agent. Methyl nitrate and other alkyl nitrates exist as pollutants in the atmosphere and participate in photochemical reactions that lead to smog formation.

2.1 Physical Properties of Methyl Nitrate

The physical properties of methyl nitrate have been thoroughly investigated because it often serves as a model compound for more complex nitrate esters with greater importance. The physical properties of methyl nitrate are summarized in Table 13.

Table 13: Physical properties of methyl nitrate.

Property	SI units		Other units		References
Molecular mass	77.0394 g/mol	12.98 mol/kg			[73]
Freezing point	190.6 K		−82.5 °C		
Boiling point	338 K		65 °C	149 °F	[74]
	338.15 K		65 °C		[75]
Density	1.217 g/cm ³		1.217 g/cm ³		[74]
Triple point	190.2 K		−82.9 °C		[76]
Heat capacity	157.19 J mol ^{−1} K ^{−1}		276.6 cal mol ^{−1} °C ^{−1}		[76]
Enthalpy of formation, liquid	−155.8 kJ/mol	−2023.6 kJ/kg	−37.24 kcal/mol	−483.6 cal/g	[74]
Enthalpy of formation, vapor	−122 ± 1 kJ/mol	−1583 ± 13 kJ/kg	−29.16 kcal/mol	−378.5 cal/g	[73]
Heat of evaporation	34.8 kJ/mol	451.7 kJ/kg	8.3 kcal/mol	107.9 cal/g	[11]
	34.10 kJ/mol	442.6 kJ/kg	8.15 kcal/mol	105.8 cal/g	
Heat of fusion	8.242 kJ/mol	107 kJ/kg	1.97 kcal/mol	25.6 cal/g	

The vapor pressure of methyl nitrate can be calculated from the equation

$$\log p = 26.6767 - 6.3431 \log T - 2620.1139/T$$

where p is the vapor pressure in mm Hg and T is the temperature in kelvin [11]. Additional properties of methyl nitrate and other alkyl nitrates are discussed in [77, 78].

2.1.1 Infrared Absorption Spectra of Methyl Nitrate

Along with publications on the IR spectra of methyl nitrate, there is a large number of publications on the absorption spectra of methyl nitrite that were not included in the current section. Methyl nitrite is only of interest as an atmospheric pollutant and as an isomer to nitromethane (NM), but would not be used as a rocket propellant.

Methyl nitrate is a relatively simple and symmetric molecule but the IR spectrum is nevertheless complex with many absorption bands. The two halves of the molecule rotate freely around the C–N axis. In the IR spectrum of methyl nitrate, the stretching vibrations of the C–H bond appeared in the 3020–2800 region. Three calculated frequencies (3011, 2959, and 2853 cm^{-1}) corresponded to three measured bands in this region [79].

The IR spectrum of methyl nitrate has been reinvestigated [80]. A few errors in previous assignments were corrected (notably the CH stretching modes that are now assigned as $\nu_1 = 3034.1 \text{ cm}^{-1}$, $\nu_2 = 2961.5 \text{ cm}^{-1}$, and $\nu_{13} = 3014.5 \text{ cm}^{-1}$ and the methyl deformation ν_{15} , assigned to 1155.7 cm^{-1}).

A typical IR spectrum of methyl nitrate is shown in Figure 5. Near 3000 cm^{-1} , three peaks occurred in the IR absorption of the liquid but only two peaks were observed in the vapor spectrum [81].

2.1.2 Microwave Spectra of Methyl Nitrate

Microwave spectra of methyl nitrate help to identify the structure of this molecule and complement measurements in other ranges of the electromagnetic spectrum in the IR range. The ground-state rotational constants of methyl nitrate measured by microwave absorption showed that the five heavy nuclei of the molecule lie in the same plane [82,

83]. The hydrogen atoms of the methyl group are found to be staggered with respect to the nearest oxygen of the —NO_2 group. Stark effect measurements gave a dipole moment of 3.10 ± 0.05 D. Data seemed to indicate a significant amount of double-bond character in the CO—N bond. The barrier to internal rotation of the methyl group, as determined from torsional satellite splittings, was 2321 cal/mol. A large discrepancy existed between the experimental and statistical entropies, the reason for which was not clear. Interpretation of this requires inclusion of the —NO_2 group torsion.

The microwave spectra of the normal species and seven isotopic species of methyl nitrate gave data for a detailed structure of the molecule, which has a planar heavy-atom skeleton, with the methyl group staggered with respect to the *cis* oxygen atom [84, 85]. The molecular structure is $\text{C—O}' = 1.437$ Å, $\text{N—O}' = 1.402$ Å, $\text{N—O}(\text{cis}) = 1.205$ Å, $\text{N—O}(\text{trans}) = 1.208$ Å, C—H (in plane) = 1.088 Å, C—H (out-of-plane) = 1.095 Å, $\angle \text{O}'\text{CHi} = 103.4^\circ$, $\angle \text{O}'\text{CHO} = 110.4^\circ$, $\angle \text{HOCHO} = 109.8^\circ$, $\angle \text{CO}'\text{N} = 112.72^\circ$, $\angle \text{O}'\text{NO}(\text{cis}) = 118.10^\circ$, $\angle \text{O}'\text{NO}(\text{trans}) = 129.52^\circ$. The methyl and nitro groups are tilted away from each other; the former is inclined at 4.8° to the $\text{C—O}'$ bond direction, and the latter at 2.9° to the $\text{N—O}'$ direction. The components of the dipole moment determined from Stark effect measurements were $\mu_a = 3.07$ D, $\mu_b = 0.235$ D, $\mu_t = 3.08$ D, and similar measurements on the *trans*- ^{18}O species have shown that the dipole moment in the normal species is oriented at 39.6° to the bridging $\text{N—O}'$ bond. The structure and bonding of methyl nitrate relates to nitric acid as methyl formiate does to formic acid.

2.1.3 Molecular Structure of Methyl Nitrate

The molecular structure of methyl nitrate has been derived from Raman spectra and electron diffraction experiments and discussed in terms of the adjacent charge rule in comparison to methyl azide and nitroxyl fluoride [86]. The molecular structure of methyl nitrate is shown in Figure 6.

Figure 6: Molecular structure of methyl nitrate

A comparison of measured Raman frequencies with those calculated from various molecular models indicated that the methyl nitrate molecule is not plane but it has a coplanar plane of symmetry (symmetry group C_s) [87]. The atoms O—NO₂ are in one plane and the C atom is in a plane perpendicular to this; the latter plane is the plane of symmetry of the molecule. The C—O—N angle is approximately 116°. The NO₂ group in methyl nitrate has the same structure as in HNO₃.

Electron diffraction studies led to the following structure for methyl nitrate, similar to that shown above [75]:

Based on an *ab initio* study on the intermolecular interaction and thermodynamic properties of methyl nitrate in the vapor phase, methyl nitrate may associate to dimers [88]. The thermodynamic properties of methyl nitrate and its dimers have been calculated based on vibrational analysis and statistical thermodynamics.

Ab initio calculations of the structure and harmonic force field of methyl nitrate have been computed and assignments of the experimental frequencies of CH₃ONO₂ and CD₃ONO₂ were made using quantum-mechanical force constants, which suggested a reassignment of the $\delta(\text{NO}_2)$ and $\rho r(\text{NO}_2)$ vibrations of CD₃ONO₂ [89]. Taking into account these new vibrational assignments, a refined harmonic force field for methyl nitrate was computed using a least-squares technique. See also [79].

2.1.4 Solubility and Miscibility of Methyl Nitrate

Methyl nitrate is slightly soluble in water and miscible with methanol, ethanol, or diethyl ether. Methyl nitrate and methanol form an azeotrope with a composition of 75% methyl nitrate and 25% methanol. This mixture has a boiling point of 330.6 K (57.5 °C). The advantage for the safety of such a mixture is that on evaporation it does not leave the sensitive 100% methyl nitrate behind.

Methyl nitrate in mixture with 20–25% methanol was tested as a monopropellant in rocket engines (*Encyclopedia of Monopropellants*). This mixture became known under the code name *Myrol*.

2.1.5 Thermodynamic Properties of Methyl Nitrate

The heat of formation of methyl nitrate vapor is $\Delta H_f^\circ \text{gas} = -122 \pm 1 \text{ kJ/mol}$ [90]. The entropy of liquid methyl nitrate is $S^\circ_{\text{liquid}} = 216.98 \text{ J mol}^{-1} \text{ K}^{-1}$ [76]. The heat capacity of liquid methyl nitrate at 298 K is $157.19 \text{ J mol}^{-1} \text{ K}^{-1}$. The heat of evaporation of methyl

nitrate at its NBP is $\Delta H^\circ_{\text{vap}} = 31.5 \text{ kJ/mol}$ [11] (Table 14). The enthalpy of fusion at 190.2 K is 8.242 kJ/mol, and the entropy of fusion at 190.2 K is $43.33 \text{ J mol}^{-1} \text{ K}^{-1}$, see [76].

Table 14: Corrected enthalpy of evaporation of methyl nitrate.

	ΔH_{vap} at 298 K		ΔH_{vap} at NBP		ΔS_{vap}	
	kJ/mol	cal/mol	kJ/mol	cal/mol	$\text{J K}^{-1} \text{ mol}^{-1}$	$\text{cal } ^\circ\text{C}^{-1} \text{ mol}^{-1}$
Methyl nitrate	34.1	8150	31.5	7540	93.3	22.3

2.2 Chemical Properties of Methyl Nitrate

Methyl nitrate has an oxygen balance of -10.4% and thus requires only little oxidizer to make a stoichiometric mixture. However, for optimum rocket performance it is not necessary to operate with stoichiometric mixtures. A slight fuel excess will usually result in better rocket performance. Methyl nitrate has found application as an ingredient in rocket propellants only once.

2.2.1 Rapid Decomposition of Methyl Nitrate

Although our primary interest is in methyl nitrate, a few papers dealing with methyl nitrite are interspersed here for comparison. Methyl nitrite is an intermediate product of methyl nitrate decomposition. Methyl nitrite is an isomer of NM. The thermal decomposition of methyl nitrite in excess argon was studied behind both incident and reflected shock waves [91]. Kinetic data were obtained in the temperature range 715–1118 K and total pressure range 0.8–5 atm. The reaction

was found to be unimolecular in nature and occurring in the low-pressure region, with a rate constant expression

$$k = 10^{16.36 \pm 0.22} \exp(-30400 \pm 850/RT) \text{ cm}^3 \text{ mol}^{-1} \text{ s}^{-1}$$

giving the best least-squares fit to the data.

The decomposition of methyl nitrate (0.25–1.75% in argon at 880–1250 K and 2.8–18.6 atm) behind incident shock waves was measured by monitoring visible and UV absorptions in the reacting gas was observed to occur in two distinct stages. The initial dissociation and subsequent fast reactions of the methoxy radical occurred almost instantaneously at the shock front [92]. This was then followed by a much slower reaction involving decomposition of formaldehyde in the presence of nitrogen oxides. The kinetics of this second reaction showed a total order of slightly less than 2.0 and

an apparent activation energy of about 100 kJ/mol (24 kcal/mol). Second-stage rates for ethyl nitrate (1.0% in argon) were virtually identical to those for methyl nitrate, even though much less NO₂ is present in the case of ethyl nitrate. Second-stage reactions did not occur below about 800 K. Modeling calculations showed that at these temperatures, methoxy radicals will dissociate in the first reaction stage, rather than disproportionate as at lower temperatures. In the second stage of reaction, NO₂ interrupts the normal chain decomposition of formaldehyde to produce OH radicals, which then propagate the chain by hydrogen abstraction from formaldehyde. It is proposed that direct attack of formyl radicals on formaldehyde, i.e.,

or

may be the dominant pathway for formaldehyde decomposition (in the absence of NO₂) for temperatures too low for fast unimolecular dissociation of HCO.

The rapid decomposition of methyl nitrate and other alkyl nitrates in shock waves is a good method to obtain kinetic rate data for fast decomposition rates for relatively simple reactions [93, 94].

2.2.1.1 Methyl Nitrate Decomposition Mechanisms

Methyl nitrate, the lowest member in the family of alkyl nitrates, is often used as a model substance to study the decomposition mechanisms of more complex alkyl nitrates. These studies have only academic value because methyl nitrate has not seen any application in rocket engines.

The proposed first step for the thermal decomposition of methyl nitrate is the homolysis of the N–O bond:

At 483–513 K (210–240 °C) and 666–2000 Pa (5–15 mm Hg), the thermal decomposition of methyl nitrate is unimolecular and the chemical equation is

The rate constant for thermal decomposition of methyl nitrate in the temperature range 483–516 K is [95, 96]

$$k = 2.50 \times 10^{14} \exp(-165000/RT)$$

where k is the rate constant in s⁻¹, R is 8.314472 J mol⁻¹ K⁻¹, and T is the temperature in kelvin. The activation energy is 165 kJ/mol. Above 513 K (240 °C) more complete decom-

position takes place, and between 529 and 597 K (256 and 324 °C) an explosion with an induction period follows the equations

and

From the change in the induction period as a function of pressure and temperature, surface area/volume ratio and the effect of addition of inhibitors such as NO_2 , it was concluded that the explosion is a thermal explosion.

The following decomposition mechanism was proposed for methyl nitrate:

To decide which of these mechanisms is rate determining, one must use isotope labeling, identify short-lived intermediates spectroscopically, or use a computer-based prediction method.

Two DFT computational methods were used to predict some possible decomposition pathways for methyl nitrate [97]. Two likely routes were found to be (a) loss of NO_2 , followed by eventual rearrangement to $\text{H}_2\text{C}-\text{OH}$,

or (b) formation of $\text{H}_2\text{C}=\text{O}$ and HONO :

The initial energy requirement for each process was about 167 kJ/mol (40 kcal/mol), and the second was exothermic, $\Delta H = -67$ kJ/mol = -16 kcal/mol of $\text{H}_3\text{CO}-\text{NO}_2$. The computation was found to underestimate the $\text{H}_3\text{CO}-\text{NO}_2$ and $\text{H}_3\text{C}-\text{ONO}_2$ dissociation energies by about 29.3 kJ/mol (7 kcal/mol). A third, less likely, route would split the C—O bond directly

The thermal decomposition of methyl nitrate vapor can transition to a detonation [98, 99]. See also [100].

2.2.2 Autoignition of Methyl Nitrate Vapor

The P - T_{autoign} ignition boundary of the thermal decomposition of methyl nitrate at low pressures in a closed vessel and the resultant self-heating leading to ignition in a spherical, Pyrex-glass reaction vessel ($V = 1088 \text{ cm}^3$, $r = 6.4 \text{ cm}$) over a wide temperature range (510–650 K) has been measured [101]. Explosion at the highest pressures studied (4 kPa) was made more difficult by convection. In all circumstances ignition did not occur instantly on gas entry. An induction time was observed and several pre-reactions may take place simultaneously during the delay. The overall activation energy for the fast reaction varied, and it corresponded to an overall activation energy of $142 \pm 8 \text{ kJ/mol}$. The half-life for methyl nitrate decomposition decreased 1000-fold over the whole temperature range. Whereas at low temperatures ignition instability appeared to be controlled by the rate of O–N bond fission, at high temperatures secondary reactions of the molecular products of decomposition become more important. In comparison, the activation energy of the slow, isothermal decomposition of methyl nitrate is only $E_{\text{act}} = 151 \pm 3 \text{ kJ/mol}$ [102], which is appreciably lower than that obtained by Appin, Khariton, and Todes [95] from slow-decomposition studies ($E_{\text{act}} = 165 \text{ kJ/mol}$). The decomposition of methyl nitrate vapor, when it ignites spontaneously at 573 K (300 °C), follows the equation

2.2.3 Computations of Methyl Nitrate Hydrolysis and Decomposition

The high-temperature decomposition of methyl nitrate was modeled by a kinetic model, assuming activation energies obtained from other sources [103] and rate-of-decomposition data obtained from decomposition of methyl nitrate in shock waves [94].

A semiempirical molecular orbital computational method has been employed to investigate the mechanism of the alkaline SN_2 hydrolysis of methyl nitrate and the influence of solvents on the hydrolysis reaction [104, 105]. The activation energy calculated was 50.6 kJ/mol for hydrolysis in the gas phase; however, when the solvent effect was taken into account, it increased to 89.6 kJ/mol, in agreement with the experimental result (82.4 kJ/mol). It was shown that the solvation energy is an important segment of the activation energy.

Although methyl nitrate and ethyl nitrate are not (normally) found in standard minimum-smoke rocket propellant formulations, they are the simplest organic nitrate esters and suitable for modeling the decomposition of alkyl nitrates as a family. Various measurements of their decomposition and combustion have been published. A computational method was developed to characterize postulated (unimolecular) thermal decomposition pathways for the decomposition of methyl nitrate or ethyl nitrate [106]. Thermochemical properties and reaction path parameters were estimated on the basis of results from *ab initio* and DFT-based quantum chemistry models. Those data were then utilized in conjunction with (1) the principles of thermochemical kinetics, (2) transition state theory/variational transition state

theory, and (3) quantum theory with master equation analysis to develop rate expressions for elementary reactions. Combined with a set of rate expressions for small-molecule reactions that were developed for modeling other systems, a detailed mechanism for the pair was assembled.

2.2.4 Photolysis of Methyl Nitrate

All studies of the photolysis of methyl nitrate have been conducted with highly diluted samples simulating the processes taking place in a polluted atmosphere. For us it would be interesting to study the laser ignition of methyl nitrate if it was to be used as a rocket propellant (again).

Atmospheric photodissociation rate coefficients and photodissociation lifetimes for NM, methyl nitrite, and methyl nitrate were calculated as a function of altitude from their measured visible and near-UV photoabsorption cross sections at 298 K [107]. The lifetime of methyl nitrite is nearly independent of altitude and is approximately 2 min. From 0 to 50 km the lifetime of NM varies from 10 to 0.5 h, while that of methyl nitrate changes from 5.3 to 0.09 d, respectively.

The photodissociation dynamics of methyl nitrate has been investigated at 193 nm by examining the products from the primary dissociation channel, namely $\text{CH}_3\text{O}^\bullet$ and $^\bullet\text{NO}_2$ [108]. The $\text{CH}_3\text{O}^\bullet$ photoproducts were probed by laser-induced fluorescence under both nascent and jet-cooled conditions. The NO_2 fragment is produced electronically excited with internal energies extending to the $\text{NO} + \text{O}$ dissociation limit.

Quantum yields were measured for the NO_2 formation channel ($\text{RO}^\bullet + ^\bullet\text{NO}_2$) following photodissociation of methyl nitrate or IPN at the tropospherically relevant wavelengths of 308–320 nm [109]. Measurements were made using UV laser absorption and cavity ring-down spectroscopy detection of the NO_2 photoproducts. Photodissociation quantum yields were measured to be unity for both methyl nitrate and IPN at wavelengths of 308, 315, and 320 nm in the presence of N_2 bath gas at pressures of up to 700 Torr and at a temperature of 294 K.

A laboratory study of the gas-phase photolysis and $^\bullet\text{OH}$ -initiated reactions of methyl nitrate and ethyl nitrate with a focus on elucidating the detailed photochemical reaction mechanisms of alkyl nitrates in the atmosphere gave unexpectedly high yields of HNO_3 and peroxyacyl nitrates such as $\text{CH}_3\text{C}(\text{O})\text{OONO}_2$ [110]. The results implied that alkyl nitrates could potentially serve as a sink for reactive nitrogen in the atmosphere. An attempt was made to estimate the production of HNO_3 and peroxyacyl nitrates derived from NO_x by alkyl nitrates as intermediates in the atmosphere.

2.3 Handling and Safety Properties of Methyl Nitrate

2.3.1 Toxicity of Methyl Nitrate

The physiological action of methyl nitrate is similar to that of GTN and other alkyl nitrates. If inhaled accidentally, it causes headaches, but the headaches subside more quickly than those caused by GTN.

2.3.2 Explosive Properties of Methyl Nitrate

Methyl nitrate and its mixtures with methanol, nitrobenzene, or benzene were used in Germany toward the end of World War II (WWII) as explosives in war heads, mines, torpedoes, and grenades. Several Myrol manufacturing plants were built in Germany toward the latter half of WWII and the nominal capacity was reported to have been near 20000 tons per month. A single installation could produce as much as 400 tons per month.

For use as a plastic explosive, methyl nitrate or Myrol was gelled with a few percent of nitrocellulose. Adding as much as 25% nitrocellulose would form a hard gel.

2.3.2.1 Shock Sensitivity of Methyl Nitrate

In the Bundesanstalt für Materialforschung und -prüfung (BAM) impact sensitivity test apparatus the impact sensitivity of methyl nitrate was 0.2 N·m. In another drop weight sensitivity test apparatus with a 2-kg mass, methyl nitrate exploded at 40 cm (for comparison: GTN 4 cm). In the BAM friction sensitivity test apparatus methyl nitrate showed no reaction at piston loads up to 353 N.

2.3.2.2 Adiabatic Compression Sensitivity of Methyl Nitrate

In a U-tube apparatus with variable, preselected push pressure and constant bubble size, the push pressure required to explode methyl nitrate was the lowest in a group of 20 energetic liquids tested [111]. Only methyl nitrate and allyl nitrate were more sensitive than GTN. The adiabatic compression sensitivity of these compounds depends on the degree of dissolved gas saturation.

2.3.2.3 Autodecomposition Temperature and Diluent Effects of Methyl Nitrate

The decomposition of methyl nitrate, air, and water vapor mixtures heated to 473 K (200 °C) and ignition by hot wire at 373 K (100 °C) was studied for methyl nitrate concentrations from 15 to 35%, air from 15 to 45%, and steam from 20 to 65% [112]. Ignition with explosion was observed for 24% methyl nitrate, 29% air, and 47% H₂O, and for 30% methyl nitrate, 15% air, and 55% H₂O. Combustion without explosion on ignition was observed for other mixtures. Air saturated with H₂O and methyl nitrate over liquid methyl nitrate was ignited in a lead block and produced sympathetic detonation of the liquid below. With a protective layer of H₂O covering the methyl nitrate, a detonation

of the liquid did not occur. Heating to 473 K (200 °C) (no hot wire) caused only slow decomposition and no explosions.

The spontaneously explosive decomposition of methyl nitrate vapor over the temperature range 523–589 K was measured using fine thermocouples and fast-response recorders [113]. Product analysis gave the stoichiometry and thermochemistry of the subcritical decomposition of methyl nitrate as

Indirect tests for a thermal explosion were applied to the spontaneous ignition of methyl nitrate, and critical initial reactant pressures could be correlated on the basis of thermal theory. A prediction that the critical partial pressure of diluted reactant should be directly proportional to the thermal conductivity of the mixture was only approximately satisfied. Self-heating was always observed, and ignition could not occur without it. The maximum subcritical rises measured in a cylindrical vessel were about 18 K, and in a spherical vessel they were about 40 K.

2.4 Explosive Performance of Methyl Nitrate

In the lead block test, detonation of methyl nitrate caused an increase of the cavity volume by 610 cm³/10 g, which is a very respectable number. The brisance in the lead block test was 132% of that of GTN. Other sources reported 102.5% of that of GTN for a 10-g sample with water tamping. The detonation velocity of methyl nitrate confined in a steel tube is 6300 m/s = 20700 ft/s at $\rho = 1.217 \text{ g/cm}^3$.

Methyl nitrate confined in a glass tube can detonate in three different ways, depending on sample diameter and method of initiation [114]. In a 10-mm glass tube it can detonate with high velocity detonation (HVD) at 6704 m/s, stable low velocity detonation (LVD) at 2540 m/s in a similar glass tube, and unstable LVD in a 5-mm glass tube at 2140 m/s.

In similar tests, when confined in glass or metal tubes of small diameter (3 to 5 mm), the detonation velocity was low, ranging from 1890 to 2482 m/s, vs. 1500 m/s for GTN. When confined in a glass tube with 20-mm diameter and 1-mm wall thickness, the detonation velocity was 6600 m/s. According to some authors, values up to 8000 m/s should be obtainable in tubes with a diameter of 30–40 mm.

3 Ethyl Nitrate

3.1 Physical Properties of Ethyl Nitrate

Ethyl nitrate, $\text{C}_2\text{H}_5\text{NO}_3$, CAS RN [625-58-1], is a colorless, volatile, highly flammable liquid. It is used in organic synthesis and as an intermediate in the preparation of some drugs, dyes, and perfumes. It is unlikely that ethyl nitrate will be used as a rocket propellant, but it has been used in mixtures with propyl nitrate as a gas generant for auxiliary power units, and it can serve as a model substance for the study of the entire family of alkyl nitrates, some of which have been used as gas generants. Physical properties of ethyl nitrate are summarized in Table 15.

Table 15: Physical properties of ethyl nitrate.

Property	SI units	Other units	References
Molecular mass	91.0660 g/mol	10.98 mol/kg	[73]
Freezing point	171 K	$-102^\circ\text{C} = -151.6^\circ\text{F}$	[115]
Melting point	178.6 K	-94.5°C	[116]
Boiling point	361.8 K	$88.7^\circ\text{C} = 191.7^\circ\text{F}$	[115]
Boiling point	362 K	89°C	[116]
Density (at 22°C)		1.105 g/cm^3	[115]
Index of refraction $n_D^{21.5}$	1.38484		
Enthalpy of formation, liquid	$-190.4 \text{ kJ/mol} =$ -2091 kJ/kg	$-45.49 \text{ kcal/mol} =$ -499.5 cal/g	[74]
Enthalpy of formation, vapor	-155.0 kJ/mol	-37.05 kcal/mol	[117]
Enthalpy of formation, liquid	-190.4 kJ/mol	-45.5 kcal/mol	[118]
Enthalpy of formation, vapor	-154.0 kJ/mol	-36.80 kcal/mol	[118]

The vapor pressure of ethyl nitrate can be represented by an Antoine equation,

$$\log_{10} p = 7.145 - 1329/(t + 224.0)$$

where p is the vapor pressure in mm Hg and t is the temperature in $^\circ\text{C}$ [119]. From the vapor pressure curve a heat of evaporation can be calculated, and it is $36.4 \text{ kJ/mol} = 8.7 \text{ kcal/mol}$ at $298 \text{ K} = 25^\circ\text{C}$ and $33.9 \text{ kJ/mol} = 8.1 \text{ kcal/mol}$ at the NBP at $360.8 \text{ K} = 87.7^\circ\text{C}$. The Trouton constant is $92 \text{ J K}^{-1} \text{ mol}^{-1} = 22 \text{ cal } ^\circ\text{C}^{-1} \text{ mol}^{-1}$. The enthalpy of formation of ethyl nitrate vapor at $298 \text{ K} = 25^\circ\text{C}$ is $-155 \text{ kJ/mol} = -37.0 \text{ kcal/mol}$. See also [120, 121].

3.1.1 Optical Properties of Ethyl Nitrate

3.1.1.1 Infrared Spectra of Ethyl Nitrate

The far-IR spectra of gaseous and solid ethyl nitrate have been recorded from 500 to 50 cm^{-1} to determine the relative proportions of *gauche* and *trans* conformers and the energy barriers for transitions from one form to the other [122]. The results of a variable-temperature Raman study indicated that the *trans* conformer is more stable than the *gauche* conformer by $328 \pm 96\text{ cm}^{-1}$ ($938 \pm 275\text{ cal/mol}$).

A vibrational assignment for the normal vibrational modes of gaseous, liquid, and solid ethyl nitrate was proposed based on Raman spectra ($4000\text{--}10\text{ cm}^{-1}$), depolarization values, group frequencies, and normal coordinate calculations [123]. The structures for the *trans* and *gauche* conformers were determined from *ab initio* Hartree-Fock gradient calculations. The energy difference between the more stable *trans* conformer and the higher-energy *gauche* conformers was found to be 474 cm^{-1} (1.36 kcal/mol). The *trans* to *gauche* and *gauche* to *gauche* barriers were 990 cm^{-1} (2.83 kcal/mol) and 3152 cm^{-1} (9.01 kcal/mol), respectively. Barriers to internal rotation for the CH_3 and NO_2 groups were also obtained from *ab initio* calculations. For the *trans* conformer the values were 1304 cm^{-1} (3.73 kcal/mol) and 2702 cm^{-1} (7.73 kcal/mol), and for the *gauche* conformer they were 1161 cm^{-1} (3.32 kcal/mol) and 2758 cm^{-1} (7.89 kcal/mol) for the CH_3 and NO_2 rotational barriers, respectively. The IR spectrum of ethyl nitrate is shown in Figure 7.

Figure 7: IR Spectrum of ethyl nitrate. (Reproduced and modified with permission from [124])

3.1.1.2 Ultraviolet Spectra of Ethyl Nitrate

The photoabsorption spectra of gaseous ethyl nitrate, NPN, 2-propyl nitrate, and *n*-butyl nitrate were measured in the laboratory at room temperature for $\lambda \geq 185$ nm [125]. The spectra were continuous and exhibited low- and high-intensity absorption bands. The maximum for the high-intensity band occurred at 188 ± 2 nm. Atmospheric photodissociation rate coefficients for alkyl nitrates were estimated in the range 0–50 km and were found to have a strong dependence on altitude. Photodissociation lifetimes were on the order of days and hours for the troposphere and stratosphere, respectively. Compared with the reaction with $\cdot\text{OH}$, photodissociation is the dominant removal process for alkyl nitrates throughout the atmosphere.

3.1.2 Thermodynamic Properties of Ethyl Nitrate

The standard enthalpy of formation at 298 K (25 °C) of liquid ethyl nitrate, -191 kJ/mol (-45.7 kcal/mol), and of gaseous ethyl nitrate, -155 kJ/mol (-37.0 kcal/mol), derived from vapor pressure measurements and IR spectra, was later substantiated from the heat of combustion which resulted in a standard enthalpy of formation of liquid ethyl nitrate of -190.4 ± 1.0 kJ/mol (-45.51 ± 0.25 kcal/mol) [126].

The recommended enthalpy of formation of liquid ethyl nitrate is $\Delta H_f^{298} = -191.6 \pm 3.3$ kJ/mol = -45.8 ± 0.8 kcal/mol, and the entropy of formation is $\Delta S_f^{298} 494 \text{ J K}^{-1} \text{ mol}^{-1} = 118.1 \text{ cal } ^\circ\text{C}^{-1} \text{ mol}^{-1}$ [116].

3.1.3 Molecular Structure of Ethyl Nitrate

The existence of two rotational isomers (“rotamers”) of ethyl nitrate has been confirmed by gas phase microwave spectroscopy [127]. The isomers were designated *trans* and *gauche* to indicate the relative positions of the $-\text{CH}_3$ and $-\text{NO}_2$ groups. The rotamers of ethyl nitrate are illustrated in Figure 8.

Figure 8: Conformations of *trans* and *gauche* rotamers of ethyl nitrate.

In the *trans* form all the heavy atoms lie in a plane. The *gauche* form differs from the *trans* by a rotation about the C–O bond of 95° and by an opening of the $\angle \text{CON}$ angle

by $\approx 3^\circ$. Both changes appear to indicate considerable non-bonded interaction of the $-\text{CH}_3$ and $-\text{NO}_2$ groups. Stark effect measurements determined the dipole moments to be: $\mu_{\text{trans}} = 3.39 \text{ D}$ and $\mu_{\text{gauche}} = 3.23 \text{ D}$. The *gauche* form is less stable by $143 \pm 70 \text{ cm}^{-1}$. The bond distances and angles in Figure 9 are color coded.

Figure 9: Molecular structure of ethyl nitrate (*gauche* configuration).

The molecular geometry of ethyl nitrate has been determined by gas-phase electron diffraction and *ab initio* molecular orbital calculations [128]. There was reasonable agreement between the experimental and computed structures and also with the rotational constants from a previous microwave study. Both *anti* and *gauche* forms were present at 310 K with the *anti* form prevailing. The following bond lengths and bond angles were obtained for the *anti* form: $\text{C}-\text{O} 1.444 \pm 0.004 \text{ \AA}$, $\text{N}-\text{O} 1.406 \pm 0.004 \text{ \AA}$, $\text{C}-\text{C} 1.520 \pm 0.004 \text{ \AA}$, $\text{N}-\text{O}(\text{mean}) 1.208 \pm 0.003 \text{ \AA}$, $\angle \text{CON} 113.0 \pm 0.6^\circ$, $\angle \text{ONO}(\text{anti}) 112.2 \pm 1.0^\circ$, $\angle \text{ONO}(\text{syn}) 118.2 \pm 0.7^\circ$, $\angle \text{CCO} 106.0 \pm 1.0^\circ$. The angles of torsion are $\varphi_{\text{anti}} 5.4 \pm 3.0^\circ$ and $\varphi_{\text{gauche}} 104 \pm 8^\circ$; an angle of 0° corresponds to the *anti* form. The nitrogen bond configurations were similar in ethyl nitrate, methyl nitrate and nitric acid. The most important *anti/gauche* parameter difference appears in the $\angle \text{CCO}$ bond angle; this angle being some 7° smaller in the *anti* form than in the *gauche* form.

The geometries, total energies, and electronic structures of ethyl nitrate and its dimers have been calculated by using an *ab initio* method [129]. All the binding energies have been corrected by the basis set superposition error and zero point energy. The greatest corrected dimer binding energy was 11.46 kJ/mol . Charge transfer between two subsystems was small. Based on vibrational analysis, the changes of thermodynamic properties from monomer to dimer have been calculated using a statistical thermodynamic method. See also: [130, 131].

3.2 Chemical Properties of Ethyl Nitrate

Ethyl nitrate has an oxygen balance of -61.5% and thus would require a substantial amount of oxidizer to be mixed in to make a decent near-stoichiometric monopropellant.

At one time the US Department of Defense had a military specification for an ethyl nitrate/propyl nitrate mixture MIL-E-26603 – Ethyl Nitrate-Propyl Nitrate Mixture, Pro-

pellant but it has been canceled and is no longer maintained. This indicates that there must have been an application for this propellant mixture, most likely as a gas generator for jet engine starters, but no documents about its use have survived.

3.2.1 Slow Thermal Decomposition of Ethyl Nitrate

Because ethyl nitrate is readily available, it has been often used (similar to methyl nitrate) as the model compound for studies of the thermal decomposition of nitrate esters, although it has never seen practical applications as a monopropellant by itself like the homologue propyl nitrates.

A stream of dry, oxygen-free nitrogen at atmospheric pressure was bubbled through ethyl nitrate to load it with a partial pressure of 2.4 kPa (18 mm Hg) of ethyl nitrate vapor and passed through an electrically heated glass tube at 473–523 K (200–250 °C) and the decomposition products were analyzed [132]. The dwell times were 8–38 s. The decomposition of ethyl nitrate is a first-order reaction. Incomplete decomposition showed ethanol and acetaldehyde as intermediate products. The reaction zone emitted a faint, uniform light that was visible only in a darkened room.

The thermal decomposition of gaseous ethyl nitrate has been studied at 434–474 K (161–201 °C) at pressures of a few cm Hg to below 20 cm Hg in a static test in glass bulbs [133–135]. An analytical technique was developed using the absorption spectra in the IR and visible regions that made it possible to follow the disappearance of ethyl nitrate directly. It was found that ethyl nitrite is a major product of the reaction and that methyl nitrite and NM were formed in minor amounts. Nitrogen dioxide and nitric oxide were also observed. The variations with time of ethyl nitrate, ethyl nitrite, and nitrogen dioxide have been followed quantitatively to serve as input for kinetic rate calculations. The effects of nitrogen dioxide, ethyl nitrite, and mercury on the reaction have been studied. The activation energy was initially 164.4 kJ/mol (39.3 kcal/mol) and later dropped to 153.1 kJ/mol (36.6 kcal/mol). The mechanism for nitrate ester decomposition was reexamined in light of these results, and some revisions had to be suggested. See also [136].

The effects of nitrogen dioxide, oxygen, nitric oxide, acetaldehyde, and diethyl peroxide on the thermal decomposition of ethyl nitrate at 454 K (181 °C) were studied, and the progress of the reaction was monitored by IR [137, 138]. The results of these studies have been examined in light of a mechanism proposed in an earlier paper and gave it strong support. On the basis of the proposed mechanism, it has been possible to carry out the thermal decomposition of ethyl nitrate under conditions such that the kinetics were truly first order and the activation energy and frequency factor could be properly related to the step wherein the N–O bond was broken. Addition of NO₂ lowered the rate of nitroethane decomposition to half the rate that would have been required in the absence of added NO₂. Ethyl nitrite did not affect the rate of decomposition of ethyl nitrate. Nitric oxide addition resulted in a sharp rate increase, but it was not proportional to the amount of NO added.

The primary step in the decomposition of alkyl nitrates is considered to be the breaking of the N—O bond. It was shown that such decompositions are retarded by initially added nitrogen dioxide, and it was suggested that this primary step is an equilibrium reaction [139]:

Nitric oxide, NO, is often added as a free radical getter. Reactions that can be impeded by NO addition usually involve free radicals in some of the rate-determining steps of the reactions. It has been customary to assume that NO inhibits reactions in the gas phase by the removal of active free radicals with the formation of compounds of the type RNO, where R is the radical. However, inhibition by nitric oxide may not necessarily indicate a free radical mechanism [140].

The kinetics of the thermal decomposition of ethyl nitrate in the gas phase have been studied in the temperature range 448–482 K (175–209 °C) [141, 142]. The initial rate of pressure rise has been used to deduce the first-order rate equation

$$k = 10^{14.74} \exp(-38000 \pm 380)/RTs^{-1}$$

Additional information was obtained from photometric measurements of the nitrogen dioxide concentration throughout the reaction. Ethyl nitrite has been detected in the products of the ethyl nitrate + nitric oxide reaction at 463 K (190 °C) by UV spectrophotometry, and ethyl nitrate has been detected in the products of the ethyl nitrite + nitrogen dioxide reaction at 463 K (190 °C) by GC. Standard analytical techniques showed that the final gaseous products are CO₂, CO, NO, N₂O, and N₂, with possibly a trace of hydrogen.

The principal product of ethyl nitrate decomposition is ethyl nitrite, with NM and methyl nitrite being minor products. On the basis of outdated kinetic studies that relied solely on manometric data, the following (incorrect) mechanism was proposed at one time:

Later work with improved instruments showed that ethyl nitrite is the principal product formed in the early stages of reaction, with NM and methyl nitrite occurring in minor quantities. The outdated mechanism would set an upper limit of 50% on the yield of ethyl nitrite, based on the ethyl nitrate decomposed, whereas yields as high as 75% were found. Reactions (3) and (4) can likewise be rejected since acetaldehyde, which should be a major product if the proposed mechanism were valid, is present in

the products in only very small amounts. A more complex mechanism was proposed later:

The observed lowering of the rate by the addition of nitrogen dioxide can be explained by the fact that the nitrogen dioxide accelerates the reverse of step (5). At one time, an exchange reaction between nitric oxide and ethyl nitrate was proposed:

If reaction (12) were to occur, there should be a continual increase in the rate with addition of nitric oxide, contrary to what was observed.

The reaction kinetics of ethyl nitrate decomposition by pyrolysis in a temperature range of 515–533 K (242–260 °C) were examined in a flow reactor in a stream of ethyl nitrate vapor in helium carrier gas and found to be of one-half order with respect to the reactant [143, 144]. A major portion of the organic product was a polyether, probably formed from formaldehyde. The activation energy and frequency factor were determined to be 46.8 kcal/mol and $10^{18.2} (\text{mmol/L})^{1/2} \text{s}^{-1}$, respectively. These data were consistent with a radical chain mechanism in which termination occurs through the interaction of two of the monomolecularly decomposing chain-carrying species, which is the ethoxide radical.

The fact that a decrease in volume: surface ratio and coating the interior of glass vessels with KCl will move the explosive limits up is an indication that the decomposition of ethyl nitrate is a radical mechanism. In a plain, uncoated Pyrex vessel, the kinetic rate equation was

$$k_1 = 10^{14.7} \exp(-38.3/RT) \text{s}^{-1}$$

The presence of a copper surface accelerated the thermal decomposition of ethyl nitrate [145]. Under these conditions the rate-controlling step appeared to involve the NO_2 molecule. The presence of a lead oxide surface in the glass vessel retarded the thermal decomposition of ethyl nitrate in the temperature range studied (453–493 K = 180–220 °C). It was suggested that this was due to the destruction of radicals through which the reaction normally proceeds under these conditions.

High-pressure mass spectrometric measurements were carried out to examine the mechanism of gaseous NO_3^- ion formation in pure ethyl nitrate vapor and its binary mixtures with various diluent gases [146]. An ion exchange reaction

occurring with an activation energy was reported, and evidence for collisional deactivation of the intermediate complex $\text{NO}_2 \bullet \text{C}_2\text{H}_5\text{ONO}_2$ was obtained.

Although ethyl nitrate is not (normally) found in standard minimum-smoke rocket propellant formulations, it is one of the simplest organic nitrate esters and suitable for modeling the decomposition of alkyl nitrates as a family. Various measurements of ethyl nitrate decomposition and combustion have been published. A computational method was developed to characterize postulated (unimolecular) thermal decomposition pathways for the decomposition of ethyl nitrate [106]. Thermochemical properties and reaction path parameters were estimated on the basis of results from *ab initio* and DFT-based quantum chemistry models. Those data were then utilized in conjunction with (1) the principles of thermochemical kinetics, (2) transition state theory/variational transition state theory, and (3) quantum theory with master equation analysis to develop rate expressions for elementary reactions. Combined with a set of rate expressions for small-molecule reactions that were developed for modeling other systems, a detailed mechanism for ethyl nitrate was assembled. Incorporated into a one-dimensional, two-phase burn-rate model, this mechanism yielded predictions for the rate of decomposition of ethyl nitrate at pressures from 0.1 to 6.8 MPa (1 to 68 atm) that were in reasonable agreement with measured data. See also [6].

3.2.2 Rapid Thermal Decomposition of Ethyl Nitrate

The rapid thermal decomposition of ethyl nitrate and other nitrate esters is typically examined in shock tubes, where the sample can be heated almost instantly to the desired test temperature without spending too much time at intermediate temperatures while it is warming up. The decay of the reactant and the rate of formation of intermediate and final products can usually be monitored by spectroscopic or mass spectrometric methods.

The decomposition of alkyl nitrates (0.25–1.75% in argon at 880–1250 K and 2.8–18.6 atm) behind incident shock waves as measured by monitoring visible and UV absorptions in the reacting gas was observed to occur in two distinct stages. The initial dissociation occurred almost instantaneously at the shock front [92]. This was then followed by a much slower second reaction. Second-stage rates for ethyl nitrate (1.0% in argon) were virtually identical to those for methyl nitrate, even though much less NO_2 is present in the case of ethyl nitrate. Second-stage reactions did not occur below about 800 K.

The rapid decomposition of ethyl nitrate and other alkyl nitrates in shock waves is a good method of obtaining kinetic rate data for fast decomposition rates for relatively simple reactions [94].

3.2.3 Temperature Threshold of Autodecomposition of Ethyl Nitrate

Ethyl nitrate and many other alkyl nitrates and nitroalkane vapors will autoignite once they are heated beyond a threshold temperature where autodecomposition will result in a runaway reaction, leading to ignition. The threshold temperature depends on the sample pressure, eventual diluents or inhibitors, and the surface condition of the reaction vessel.

The inflammation of methyl nitrate, ethyl nitrate, or NG vapors and the influence of different diluents on the threshold temperature were investigated over a temperature range of 513 to 773 K (240 to 500 °C) [99, 147]. The explosion of methyl nitrate is facilitated by both argon and nitrogen. With oxygen as diluent, explosive combustion occurs. The results showed that the explosion is not thermal, but due to chain branching. A glow region has been observed with MeNO_3 , EtNO_3 , or NG at below-explosion-limit marginal pressures and temperatures. These nitrates will emit a glow on admission to a hot quartz vessel, even when diluted from a thousand to a million times with inert gases. It was suggested that the glow is associated with the production of excited formaldehyde molecules. The explosion of MeNO_3 was aided over the whole temperature range by dilution with argon or nitrogen. This showed that self heating is of secondary importance and that the explosion developed by a branching-chain mechanism. The effect of surface-to-volume ratio on the explosion limit is in accord with this view if the radicals causing branching are lost principally by diffusion to the walls.

The reaction in a closed vessel would just cause a single puff. The continuing decomposition of alkyl nitrate vapors in a stationary, stabilized flame or propagation of a flame front through a shock tube will be discussed in *Encyclopedia of Monopropellants*.

3.2.4 Photolysis of Ethyl Nitrate

Ethyl nitrate and other alkyl nitrates have been found in the atmosphere and in some ocean waters. They may occur naturally or form as a result of artificial atmospheric pollution. There is a stationary equilibrium between the formation of ethyl nitrate and the photolysis of ethyl nitrate under the influence of sunlight. Most of the photolysis in alkyl nitrate studies were done for atmospheric chemistry research. None relate to its use in rocket propellants. For us it would be interesting to study the laser ignition of ethyl nitrate only if it was to be used as a rocket propellant.

Photolysis of ethyl nitrate yields a variety of products [148]. If ethyl nitrate vapor is photolyzed at 368 K (95 °C) with 2537 Å UV light, the following compounds can be found among the products: nitrogen dioxide, nitric oxide, nitrous oxide, nitrogen, NM, hydrogen, carbon monoxide, carbon dioxide, formaldehyde, and acetaldehyde. There is evidence that the ethoxy radical can break down in two ways, one forming acetaldehyde and a hydrogen atom and the other formaldehyde and a methyl radical. The methyl radical appeared to react preferentially with NO₂, forming NM.

The photolysis rate coefficient of ethyl nitrate to NO₂ and the ethoxy radical was measured using a luminol chemiluminescence NO₂ detector [149]. The photolysis of ethyl nitrate is slow: at a temperature of 288 K and a zenith angle of 60°, it is $0.45 \times 10^{-6} \text{ s}^{-1}$. At a zenith angle of 0°, it was estimated to be ca. $1.1 \times 10^{-6} \text{ s}^{-1}$. This implies a photolytic lifetime of about 1 month in the planetary boundary layer. Observed photolysis rate coefficients agree with coefficients calculated using absorption cross sections and an assumed quantum yield of unity.

The UV absorption cross sections for ethyl nitrate were measured as a function of temperature between 265 and 340 nm using cavity ring-down spectroscopy [150]. Absorption cross sections increased with temperature between 238 and 298 K. The variation with temperature was greater at longer wavelengths. Photodissociation product channels of ethyl nitrate at 308 nm were determined using an excimer laser and a cavity ring-down spectrometer. C₂H₅O and NO₂ were the sole photofragmentation products with a quantum yield of 1.0 ± 0.1 , independent of temperature.

Absorption cross sections and quantum yields for NO₂ production by photolysis of ethyl nitrate at 294 K in a wavelength range of 240–320 nm were measured [151]. NO₂ quantum yields at photoexcitation wavelengths of 290, 295, and 315 nm were unity within experimental uncertainties for all of the alkyl nitrates studied and were independent of diluent gas (N₂) pressure for total sample pressures in a range of 250–700 mm Hg.

3.2.5 Handling and Safety Properties of Ethyl Nitrate

The flash point of ethyl nitrate is 236 K = –37 °C. The lower limit of flammability of ethyl nitrate vapors in air is 4.0 vol.-% with upward propagation in a 53-mm-diameter tube that is open at the bottom [152]. The upper flammability limit is presumably at 100%. No additional oxygen is needed to sustain a decomposition flame in ethyl nitrate vapor.

3.2.5.1 Explosive Sensitivity of Ethyl Nitrate

In the card gap test with 0.050-in.-thick cardboard cards and a 20-g tetryl booster in a 27-mm-inner-diameter (ID) steel pipe, the probability of 10 failures within 10 tests was 0.458 at 43 cards [153]. In a card gap test with a 1.27-cm diameter, 10.2-cm-long steel tubes with 0.25-cm wall thickness, ethyl nitrate was positive with a 3.17-cm Plexiglas gap and negative with a 3.81-cm Plexiglas gap [154].

Ethyl nitrate and NPN were used to calibrate an adiabatic compression U-tube test apparatus in preparation for additional tests with difluoroamino compounds [155]. The 50% probability points shown in Table 16 were derived from a probit plot using the up-and-down method.

Table 16: U-Tube adiabatic compression sensitivity calibration data.

Calibrating material	Gas bubble pressurant	Initial pressure, atm	50% probability positive driving pressure ratio
Ethyl nitrate	Air	1	7.3
Ethyl nitrate	Air	2	7.9
Ethyl nitrate	Air	3	8.6
Ethyl nitrate	Air	5	8.0
Ethyl nitrate	Nitrogen	3	24
<i>n</i> -Propyl nitrate	Air	1	21
Nitroethane	Air	1	120

Data source: [155]

All tests were conducted at ambient temperature ($\sim 294\text{ K} = \sim 70^\circ\text{F}$). The average driving pressure ratio for ethyl nitrate was 7.81 ± 0.71 . The ambient pressure calibrations with ethyl nitrate were comparable to the results of both Minnesota Mining and Manufacturing Co. [156] and Air Reduction Co.

In a series of tests to study LVD, ethyl nitrate was tested in lead and steel tubes in comparison to 1,2-bis(difluoroamino)propane (1,2-DP) and a NM/tetranitromethane (TNM) mixture. The results differed depending on whether or not a witness plate was at the end of the sample. The results are shown in Table 17. Ethyl nitrate was the least sensitive compound of the three materials tested.

Table 17: LVD Gap sensitivities of ethyl nitrate in comparison to 1,2-DP and a NM/TNM mixture.

Compound	Confinement, steel tubes		LVD gap sensitivity, cm of Plexiglas	
	I. D., cm	Wall thickness, cm	Witness plate	No witness plate
Ethyl nitrate	12.7	0.23	2.54–5.4	3.8–5.1 (probe)
For comparison:				
1,2-DP	12.7	0.63	91–126	61 (camera)
TNM/NM (18.7/81.3 mass-%)	12.7	0.63	8.9–10.2	11.0 (probe)

Data source: [157]

3.2.6 Explosive Performance of Ethyl Nitrate

In the lead block test the enlargement of the cavity was $420 \text{ cm}^3/10 \text{ g}$. The detonation velocity of ethyl nitrate confined in a steel tube was 5800 m/s at a density of 1.1 g/cm^3 .

The shock initiation of ethyl nitrate was tested in comparison to GTN and TMETN [158]. The donor charges were 3.5-cm-diameter Composition B pellets, 10 to 12.5 cm in length. The spacers were 6.5×8.0 -cm square glass plates of varying thicknesses S_1 (3.2–9.3 mm), and the receptor explosive was contained in 4- to 7.5-cm-diameter glass cylinders. The initial wave velocity and delay to detonation were measured with a streak camera and were $4220 \text{ mm}/\mu\text{s}$ and the delays were 0.45–1.8 μs .

3.2.7 Applications of Ethyl Nitrate

We have often wondered why ethyl nitrate has not found the same range of examination as a rocket propellant as the two propyl nitrates described in the following section. Ethyl nitrate has a more favorable oxygen balance (–61.5% vs. –99% for the propyl nitrates) and higher specific impulse (227 vs. 207 s at $p_c = 1000 \text{ psia}$ and shifting equilibrium expansion to 14.68 psia).

4 *n*-Propyl Nitrate

There are two propyl nitrates, NPN with a straight carbon chain and IPN with a branched carbon chain. Both have been tested as rocket propellants and as liquid gas generants. They differ in their chemical reactivity and thermal stability and sensitivity to external stimuli such as impact or rapid compression. NPN is discussed here first, followed by IPN. Some references cited here treat both nitrates and other alkyl nitrates side by side. The oxygen balance of propyl nitrates is substantially fuel-rich, –99% for combustion to CO_2 . With that negative oxygen balance, one must expect that the exhaust from a rocket or gas generator operating on propyl nitrate would be very sooty. The oxygen balance for monopropellants with propyl nitrates can be improved by adding other nitrates (polynitrates) with a better oxygen content.

Either of the two propyl nitrates can be prepared by nitration of the corresponding propanol with mixed acid. The formation of unwanted nitrites is prevented by adding ~3% urea [159, 160]. It would be desirable to perform the nitration without using sulfuric acid since disposal of the spent acid is a difficult task.

Normal propyl nitrate, also known as normal propanol nitrate, 1-propanol nitrate, nitric acid propyl ester, $\text{C}_3\text{H}_7\text{ONO}_2$, NPN, CAS RN [627-13-4] is the isomer of IPN. Both nitrates have been extensively investigated and some have even been used in flight applications as rocket propellants or gas generants. NPN and other alkyl nitrates can be synthesized by the reaction of alkyl halides (iodides or bromides) with silver nitrate.

An improved method for preparation of 1-propanol nitrate from 1-propanol is using a mixture of nitric acid and ammonium-magnesium nitrate as nitrating agent which facilitates waste acid disposal [161]. Nitric acid can be recycled.

4.1 Physical Properties of *n*-Propyl Nitrate

Physical properties of NPN are available in [162] and are summarized in Table 18.

Table 18: Physical properties of NPN.

Property	SI units	Other units	References
Molecular mass	105.0926 g/mol	9.515 mol/kg	[73]
Freezing point	172 K	−101.1 °C	[115]
Boiling point	383.6 K	110.5 °C	[115]
Boiling point	383.7 K	110.6 °C	[73]
Density at 293 K	1.058 kg/L	1.058 g/cm ³	[74]
Density at 293 K	1.0573 kg/L	1.0573 g/cm ³	
Viscosity at 273 K	0.99 μPa s	0.99 cPs	[115]
Surface tension at 22.3 °C	27.02 × 10 ^{−3} N/m	27.02 dyn/cm	[115]
Refractive index n_D^{20}	1.3979		[115]
Refractive index n_D^{25}	1.3949		[163]
Dielectric constant (at 18 °C and 360 MHz)	13.9		[115]
Enthalpy of formation ΔH_{298}^f	−214.5 kJ/mol	−2041 kJ/kg −51.27 kcal/mol −487.8 cal/g	[74]

See also [164–167]. The density of NPN as a function of temperature can be calculated from the equation

$$\rho = 0.55892 - 0.00066 t + 0.77527(307 - t)^{\frac{1}{3}}$$

where ρ is the density in g/cm³ and t is the temperature in °C. The compressibility of NPN and *n*-butyl nitrate is described in [168].

Isolated vapor pressure data are from the literature: p_v at 34.5 °C = 40.2 mm Hg and at 88.1 °C = 378.1 mm Hg. The vapor pressure as a function of temperature can be calculated from the equation

$$\log p_v = 7.3506 - \frac{1520}{t + 230}$$

where p_v is the vapor pressure in mm Hg and t is the temperature in °C. A similar Antoine equation for the vapor pressure of NPN is (from NIST, based on [11] data)

$$\log_{10} p_v = 4.86209 - [1721.723 / (T - 27.66)]$$

where p_v is the vapor pressure in bar and T is the temperature in kelvin. Viscosity and surface tension data for NPN are listed in Table 19 and 20.

Table 19: Viscosity of NPN.

Temperature		Viscosity	
K	°C	μPa s	cPs
194.65	−78.5	8.1	8.1
215.15	−58.0	3.3	3.3
243.15	−30.0	1.9	1.9
273.15	0.0	0.99	0.99
303.15	30.0	0.58	0.58
313.15	40.0	0.50	0.50
333.15	60.0	0.38	0.38

Data source: [115]

Table 20: Surface tension of NPN.

Temperature		Surface tension	
K	°C	N/m	dyn/cm
290.95	17.8	27.45×10^{-3}	27.45
295.45	22.3	27.02×10^{-3}	27.02
314.05	40.9	24.45×10^{-3}	24.45
331.55	58.4	22.53×10^{-3}	22.53

Data source: [115]

4.1.1 Critical Point Data of *n*-Propyl Nitrate

The critical point properties of NPN are listed in [169].

$t_{\text{crit.}}$ about 580 K = 307 °C;

$p_{\text{crit.}}$ 3.95 MPa = 39 at,

$\rho_{\text{crit.}}$ 0.334 g/cm³.

4.1.2 Pressurant Gas Solubility

The sensitivity of nitroalkanes and alkyl nitrates to sudden compression depends on the presence of gas bubbles in the liquid. The presence of gas bubbles depends on the degree of saturation and the pressure history as the propellant flows from a reservoir through the metering and flow control device into the combustion chamber. The degree of saturation depends on the solubility of pressurant gases in the liquid at different temperatures and pressures. For this reason the solubility of gases in alkyl nitrates has been thoroughly investigated [170, 171]. The solubility of air, nitrogen and oxygen in NPN at room temperature and pressures of 0.26 to 1 atm was measured and can be expressed by

$$\begin{aligned}\text{Air} \quad S &= 5.787 \times 10^{-9}P + 4.265 \times 10^{-12}P^2 \\ \text{Nitrogen} \quad S &= 7.371 \times 10^{-9} - 7.277 \times 10^{-13}P^2 \\ \text{Oxygen} \quad S &= 7.515 \times 10^{-9} + 6.012 \times 10^{-12}P^2\end{aligned}$$

where S is the mols of gas absorbed per g of liquid and P is the total pressure in atm minus the vapor pressure of propyl nitrate. The solubility of oxygen was significantly greater than that of nitrogen. A consequence is that bubbles formed by the release of pressure during pumping of air-saturated NPN can be enriched in oxygen and more likely to react.

4.1.3 Optical Properties of *n*-Propyl Nitrate

4.1.3.1 IR Spectra of *n*-Propyl Nitrate

The IR spectrum of NPN is very similar to that of other alkyl nitrates (Figure 10). See also [172].

Figure 10: IR spectrum of NPN. (Reproduced and modified with permission from [124].)

4.1.4 Molecular Structure of *n*-Propyl Nitrate

4.1.4.1 Computational Studies of *n*-Propyl Nitrate Molecular Structure

With the increasing power of computers, the molecular orbitals and molecular structure of even more complex (containing 10 or more atoms) molecules can be calculated and used to predict absorption spectra and thermodynamic properties.

A conformational analysis of the propyl nitrate molecule by *ab initio* and DFT methods revealed seven energy minima corresponding to seven different conformers [173]. Both methods predicted that the *gauche* conformer with the $\angle\text{CCCO}$ (t_3) being twisted by about 63° had the lowest energy and was more stable than the planar conformer, but the stability order of different conformers obtained by other methods was somewhat different. The energy differences between various conformers and the barriers to internal rotation are all very low. The standard thermodynamic functions and the equilibrium mole fractions can be derived for various conformers. The calculated thermodynamic properties and heats of formation of propyl nitrate were in reasonable agreement with experimental results.

Similar calculations were performed for the molecular structures, vibrational spectra standard thermodynamic functions, and heats of formation of methyl nitrate, ethyl nitrate, NPN, IPN, butyl nitrate, EGDN, and GTN [174].

DFT methods were used to investigate the equilibrium geometry, frontier orbital energy, and energy gap, as well as BDEs, of NPN and IPN [175]. The thermal stability of the two nitrates and the corresponding radicals were analyzed. The O—NO₂ BDEs of NPN and IPN were close to the experimental values. That the experimental thermolysis of two nitrates is only unimolecular homolytical dissociation of the O—NO₂ bonds is corroborated by the finding that the present results of BDE are well coincident with the experimental results of activation energy from literature data.

4.1.5 Microwave Spectra of *n*-Propyl Nitrate

Microwave spectra of alkyl nitrates help to identify the structure of these molecules and complement measurements in other ranges of the electromagnetic spectrum in the IR range. Low-resolution microwave spectra of *n*-propyl, isopropyl, *n*-butyl, and 2-butyl nitrate revealed mixtures of conformational isomers that have been characterized and correlated with conformations observed in the simpler ethyl nitrate molecule [176]. Conformers of the three primary esters can be assigned to *anti* and *gauche* configurations about the NOCC torsional angle coupled with *gauche* or *anti* configurations about τ_3 (OCCC) and τ_4 (CCCC) for *n*-propyl and *n*-butyl nitrate. IPN was predicted to exist in a *gauche* (τ_2 (NOCH)~ 60°) conformation. For each compound all of the observed conformers were approximately equally stable. The low-resolution microwave spectra were insensitive to orientation about τ_1 (ONOC).

4.1.6 Refractive Index of *n*-Propyl Nitrate

The refractive index of NPN at 298 K (25 °C) is 1.3949 [163].

4.1.7 Magnetic Properties of *n*-Propyl Nitrate

A complete analysis of the ^1H NMR spectra of 21 nitrate esters from *n*-propyl to *n*-decyl nitrate, as well as isopropyl and isobutyl nitrates, several dinitrates, and trinitrates, was not possible [177]. The resolution was not sufficient to allow all the NMR parameters to be evaluated. It would be difficult to use NMR in the analysis of nitrate ester mixtures.

4.1.8 Thermodynamic Properties of *n*-Propyl Nitrate

Thermodynamic properties of NPN are summarized in Table 21.

Table 21: Thermodynamic properties of NPN.

Property	SI units		Other units		References
Heat capacity at 298 K (25 °C)	1.75 J K ⁻¹ g ⁻¹		0.419 cal °C ⁻¹ g ⁻¹		[169]

4.2 Chemical Properties of *n*-Propyl Nitrate

Commercial grades of NPN may contain several percent of other alkyl nitrates, depending on the source of the material. The now obsolete military specification MIL-N-8722A (US Air Force) (Publication Date: Jan 12, 1968) at one time set minimum purity requirements for NPN, but it has since been canceled and is no longer maintained.

NPN is a good solvent. It is miscible with C₁–C₄ alcohols in all mixture ratios but does not dissolve in water. Its solubility in water at 293 K (20 °C) is only 0.3 mass-%.

The oxygen balance of NPN is -99.0%, and the nitrogen content is 13.33 mass-% N.

4.2.1 Reactions of *n*-Propyl Nitrate

Alkyl nitrates are not moisture sensitive, but in alkaline conditions they will hydrolyze. Hydrolysis is a very undesirable reaction because it detracts from the energy available as propellant.

The stability of nitrate esters in 90 vol.-% ethanol containing sodium hydroxide was studied by measuring the rates of hydrolysis [178]. Initial rates of hydrolysis were determined at either 303 or 333 K (30 or 60 °C) in the case of methyl, *n*-propyl, *n*-butyl, *n*-heptyl, *iso*-butyl, and ethylene glycol mononitrates; ethylene glycol, propane 1,3-diol, butane 1,4-diol, pentane 1,5-diol, butane 1,3-diol, butane 2,3-diol, propane 1,2-diol, diethylene glycol, and triethylene glycol dinitrates; glycerol 1- and 2-mono- and 1,3-di- and trinitrates; and metriol trinitrates; and PETN and 2-nitro-ethyl nitrate. Longer alkyl substituents, with retarding inductive effects, stabilized the esters, whereas nitro, nitrate, and hydroxyl substituents in the alkyl groups (with electron-attracting properties) increased the rate of hydrolysis by increasing the ionization of α -hydrogens. The effects fell off rapidly as the distance between groups increased. Ammonium salts decreased reaction rates by combining with hydroxyl ions.

4.2.2 Thermal Decomposition of *n*-Propyl Nitrate

4.2.2.1 Slow Thermal Decomposition of *n*-Propyl Nitrate

The decomposition of NPN has been investigated in the temperature range 438–460 K (165–187 °C) using manometric techniques [179]. The reaction is first order and essentially homogeneous. The rate constant over the temperature interval studied was found to be

$$k = 10^{14.7} \exp(-36860/RT) \text{ s}^{-1}$$

Studying the decomposition of NPN vapor at 454 K (181 °C) as a function of time used the same techniques previously used by the same investigators for the decomposition of ethyl nitrate [180, 181]. The initial pressures of NPN were on the order of 20 mm Hg in a Pyrex bulb. Analyses for NPN, *n*-propyl nitrite, and nitroethane were made using the IR absorption peaks at 11.68, 12.55, and 6.31 μm , respectively. Nitrogen dioxide and nitric oxide were analyzed colorimetrically. The presence of formaldehyde in the products was indicated by its odor and by the deposition of a white deposit on the reaction walls of the glass bulb assumed to be paraformaldehyde. The study revealed that the decomposition of NPN is similar in many respects to the decomposition of ethyl nitrate. The principal products, as revealed by IR and visible region spectra, were *n*-propyl nitrite, nitroethane, nitrogen dioxide, and nitric oxide. The effect of additives upon the reaction appeared to parallel the results observed previously in ethyl nitrate decomposition. Nitrogen dioxide and oxygen inhibited decomposition, and nitric ox-

ide had an accelerating effect. The following reaction sequence was proposed:

Alkoxy free radicals play a substantial role in the decomposition of alkyl nitrates [182].

NPN is thermally stable at temperatures up to its NBP. A sample was boiled and refluxed for 10 d, and very little decomposition was noted. Decomposition in the liquid phase may be accelerated by contaminants. Commonly observed contaminants are nitrogen dioxide and acetaldehyde.

The pyrolysis of NPN at very low pressures gave for the reaction

the following high-pressure rate expression at 300 K [183]:

$$\log k_1(\text{s}^{-1}) = 16.5 - 40.0 \text{ kcal/mol} / 2.3RT$$

From various assumptions the derived $\log k$ was $\log k_{-1}(\text{M}^{-1} \cdot \text{s}^{-1})$ (300 K) = 9.5. In contrast, the pyrolysis of methyl nitrite and methyl d3 nitrite afforded NO and HNO and DNO, respectively, in what appeared to be a heterogeneous process.

The BDEs of O—NO₂ bonds in four alkyl nitrates, NPN, IPN, EHN, and TEGDN, were calculated and compared to experimental results of apparent activation energies [184]. The thermal decomposition characteristics of NPN, IPN, EHN, and TEGDN were investigated by DSC and high-pressure DSC, and the kinetic parameters of thermal decomposition were obtained. The results showed that the thermal decomposition of the four nitrates under ambient pressure occurred in the gas phase. When the pressure was increased to 2 MPa, their decomposition processes occurred in the liquid phase. Because the calculated results of O—NO₂ BDEs of the four nitrates were in good agreement with the experimental results of apparent activation energies obtained from DSC, it was concluded that the thermolysis of the four nitrates is by way of unimolecular homolytic cleavage of the O—NO₂ bonds.

The thermal stability and thermal decomposition properties of the four nitrates, that is, NPN, IPN, TEGDN, and DEGDN, were examined by ARC under adiabatic conditions [185]. The onset temperature, the initial temperature rise rate, and the maximum temperature rise rate were recorded, and the apparent activation energy and preexponential factors of the thermal decomposition were calculated. The self-accelerating decomposition temperatures of the four nitrates in three different containers (4.5-L iron drum, 25-L iron drum, and 210-L fiber drum) were calculated. It was concluded that the onset temperatures of the exothermic decomposition of

NPN, IPN, TEGDN, and DEGDN were 422.9, 429.7, 423.7, and 423.7 K (149.8, 156.6, 150.6, and 150.6 °C), respectively, while the maximum temperature rise rates of NPN, IPN, TEGDN, and DEGDN were 18.2, 12.1, 59.7, and 209.8 °C/min, with the apparent activation energy of NPN, IPN, TEGDN, and DEGDN being 214.4, 213.8, 226.4, and 214.5 kJ/mol, respectively. The thermal stability of the four nitrates was ranked (from worst to best) as DEGDN TEGDN NPN IPN.

NPN sometimes is found in the residual acid solutions (spent acid) of industrial nitration processes. Spent acid sometimes undergoes unexpected, violent decomposition reactions, which may result in industrial accidents. A mixture containing 2% NPN in white fuming nitric acid was heated in an open test tube with an immersed thermocouple, and the results were compared to those obtained by DSC with sealed crucibles [186]. Under open-air conditions, an exothermic reaction started at 338 K, and in the sealed DSC the exotherm started at 318 K.

4.2.2.2 Computational Chemistry Treatment of *n*-Propyl Nitrate Decomposition

Three different DFT methods were used to investigate the O—NO₂ bond lengths, frontier orbital energies, and O—NO₂ BDEs of NPN, IPN, EHN, TEGDN, and Tetra-EGDN [28, 187]. It was found that the O—NO₂ bond lengthened (i.e., destabilizes) in the order IPN, NPN, EHN, Tetra-EGDN, and TEGDN. From the data of frontier orbital energies it was estimated that the relative thermal stability ordering of five nitrates as expressed by predicted BDEs of O—NO₂ bonds in NPN, IPN, EHN, TEGDN, and Tetra-EGDN are 176.6, 174.5, 168.1, 156.1, and 159.3 kJ/mol, respectively. Predicted BDEs were in agreement with the experimental results of apparent activation energies from the literature, and the thermolysis of these five alkyl nitrates is predominantly by unimolecular homolytic cleavage of the O—NO₂ bonds.

The following parameters for a molecule must be known before one can predict the energy release and the path of thermal decomposition of an energetic molecule: vibrational frequencies, moments of inertia, collision cross sections, critical energy, and sterical factors. The unimolecular decomposition of NPN was used as an example for testing a new theory [188]. An attempt was made to correlate the vapor-phase decomposition with liquid strand burning rates, but it was concluded that the initial decomposition reaction of nitrate esters could not be the rate-determining step for the observed variation of liquid burning rate with pressure.

4.2.2.3 Rapid Thermal Decomposition of *n*-Propyl Nitrate

The rapid decomposition of alkyl nitrate vapors is often studied in shock tubes with reflected shock waves while monitoring reactant and product concentrations with fast spectrophotometric methods. This makes it possible to study the effects of diluents, inhibitors, and oxidants on the reaction kinetics. From this standpoint it is interesting to compare the different behavior of the isomeric NPN and IPN under these conditions.

The strand burning of liquid NPN and NPN mixtures will be discussed in *Encyclopedia of Monopropellants*.

4.2.3 Photolysis of *n*-Propyl Nitrate

Several alkyl nitrates, including NPN, have been detected in the atmosphere and in the oceans as a result of naturally occurring processes and/or anthropogenic atmospheric pollution. Under the influence of sunlight, vapors are photolyzed and form other pollutants. A dynamic equilibrium is established between the formation and photolysis of propyl nitrate(s).

The photolysis of NPN and other alkyl nitrates is discussed in this chapter because this is a method for controlled ignition of the decomposition reaction in rocket engines by laser photolysis. Photolysis determines the rate of decay of spilled propellants in surface waters under the influence of sunlight. UV photolysis is a useful method for removing wastewater from propellant production facilities.

Absorption cross sections and quantum yields for NO₂ production by the photolysis of methyl, ethyl, *n*-propyl, and isopropyl nitrate at 294 K in a wavelength range of 240–320 nm were measured [151]. NO₂ quantum yields at photoexcitation wavelengths of 290, 295, and 315 nm were unity within experimental uncertainties for all of the alkyl nitrates studied and were independent of diluent gas (N₂) pressure for total sample pressures in a range of 250–700 mm Hg. When averaged over all wavelengths and sample pressures, the values of quantum yields for NO₂ formation were near unity.

4.2.4 Storage Stability of *n*-Propyl Nitrate

4.2.4.1 Liquid-Phase Slow Decomposition

The slow decomposition of NPN during storage, its compatibility with metals, and the solubility of gases in this propellant have been measured in detail [181].

4.2.5 Analytical Methods for *n*-Propyl Nitrate

There were at one time military specifications for propyl nitrates, but they are no longer maintained, and it is difficult to obtain copies of these old, obsolete specifications, such as MIL-E-26603 – Ethyl Nitrate-Propyl Nitrate Mixture, Propellant or MIL-P-8722 – Propellant, *n*-Propyl Nitrate.

Propyl nitrate is not (was not) that widely used as a propellant ingredient or anywhere else that a large working population would be at risk of inhaling the vapors in the air or ingest it by any other means. Nevertheless, a colorimetric method for the analysis of propyl nitrate in blood was developed that was based on the reaction of alkyl nitrates with 3,4-xylenol [189]. Propyl nitrate in the presence of a 10-fold excess of inorganic nitrate and organic and inorganic nitrite was extracted from blood with petroleum ether and subsequently determined by the 3,4-xylenol method. The solvent extraction removed the interference from blood chloride and inorganic nitrate and nitrite. Shaking the extract with an aqueous solution of sulfamic acid removed the interference from organic nitrite. Recoveries averaged 92% of propyl nitrate from a 1-mL sample of blood using sulfamic acid.

4.3 Materials of Construction for *n*-Propyl Nitrate

Pure and dry NPN can be stored in steel drums for several years without any noticeable decomposition [190]. Moist NPN may corrode metal walls, but the liquid remains uncontaminated.

Steel and aluminum are acceptable materials for the construction of NPN storage containers. Copper or bronze will be stained by a green layer of corrosion products when they come into contact with NPN.

Aluminum alloy ST, soft aluminum 28, Monel K, and stainless-steel CRES 303 are well suited for use with NPN [181]. Armco cast iron is less suitable. Wrought steel 1020 is not suitable for NPN service. Polyethylene, Kel-F, Teflon, and melamine resins are NPN resistant. Polyethylene and polyisobutylene and mixtures of the two elastomers have been approved [191, 192]. The lubricants Kel-F oil, graphite, and molybdenum sulfide have been recommended for NPN service.

4.4 Handling Safety and Storage of *n*-Propyl Nitrate

For safety reasons it was recommended to subdivide NPN storage facilities into many smaller tanks, each surrounded by a berm or wall to prevent sympathetic detonations. The UN shipping designation for NPN is UN1865.

4.4.1 Transfer of *n*-Propyl Nitrate

NPN should be kept free of dissolved gases to minimize the risk of accidental explosions by adiabatic compression of bubbles. It is best to degas it by evacuating and preventing the readmission of gases. Transfer of NPN should not be done by pressurization because pressurant gases might dissolve in the liquid and render it more sensitive [170].

At one time General Electric had developed a special pump for gently pumping NPN for transfer between transportation and ground storage tanks.

Accidental explosions can be caused by pressure spikes during the transfer of explosive liquids like propyl nitrate. The pressures commonly referred to as surge pressures are as follows:

- Pressure waves caused by opening a valve between high-pressure and low-pressure domains
- Pressure surges by priming an evacuated line with liquid
- Pressure surges produced by the application of an external static load
- Pressure surges caused by deceleration of moving masses (bumping a railroad tanker car)
- Pressure waves related to pump characteristics commonly referred to as *pump ripple*

- Rapid compression of gas bubbles in contact with liquid force due to mechanical shock in a pump
- Rapid compression of gas bubbles in a pump

4.4.2 Toxicity of *n*-Propyl Nitrate

Most alkyl nitrates are vasodilators, resulting in a rapid drop in blood pressure. For this reason alkyl nitrates (and nitrites) have been used in the treatment of angina pectoris.

In dogs, the 4-h LC₅₀ of NPN vapor is 2000 to 2500 ppm [193].

NPN is of low acute dermal toxicity in rabbits. It is moderately toxic to rats following single or repeated administration by oral and inhalation routes, causing effects on the central nervous system and blood (red blood cell damage and a reduction in oxygen levels). Mice and dogs treated by inhalation also showed central nervous system and blood effects [194].

The NIOSH recommended exposure limit (REL) time-weighted average (TWA) for NPN is 25 ppm with a short-term limit of 40 ppm. The OSHA permissible exposure limit (PEL) is 25 ppm, but the short-term exposure limit (STEL) of 40 ppm was later rescinded. The American Conference of Governmental Industrial Hygienists (ACGIH) recommended threshold limit value (TLV) TWA is 25 ppm. The original Immediately Dangerous to Life or Health Concentration (IDLH) for NPN was 2000 ppm, but this was later lowered to 500 ppm. See also [65, 195].

4.4.3 Safety Properties of *n*-Propyl Nitrate

4.4.3.1 Fire Hazard Properties of *n*-Propyl Nitrate

The ignition properties of NPN in air are summarized in Table 22.

Table 22: Ignition properties of NPN in air.

Property	References
Autoignition temperature (at 1 atm)	466 K = 193 °C
Autoignition temperature	448 K = 175 °C [196]
Flammable limits (in air at 398 K = 125 °C and 101 kPa = 1 atm)	1.8 to 100 vol.-% [196]
Flash point, open cup	299.8 K = 26.7 °C
Flash point, closed cup	293 K = 20.0 °C

For additional information on the safety properties of NPN see [39, 197–200].

In evaluating fire and explosion hazards, it is the lowest temperature at which ignition can accidentally occur that is of interest. The spontaneous ignition temperature, or autoignition temperature (AIT), is determined in a uniformly heated apparatus that is sufficiently large to avoid wall quenching effects. The time from reaching

Figure 11: Time delay before autoignition of NPN in air at 6.8 MPa. (Reproduced and modified from [196].)

temperature to the point of ignition is the delay time, and it is temperature and pressure dependent. Figure 11 illustrates typical autoignition-temperature data. In Figure 11 the minimum AIT value for NPN is 443 K (170 °C) at an initial pressure of 6.8 MPa (1000 psig). If one plots the logarithm of the delay time vs. reciprocal absolute temperature, the activation energy can be derived from the slope of the straight line.

Materials like alkyl nitrates that are oxidized or decomposed readily may yield erratic flammability limit data under certain conditions. This effect is illustrated in Figure 12, which summarizes the lower flammability limit (LFL) data with NPN in air at various temperatures and pressures [199]. An increase in temperature from 348 to 398 K (75 to 125 °C) was accompanied by a modest decrease in the lower limit values; a further increase in temperature to 423 K (150 °C) resulted in a further lowering of the lower limit at pressures below 100 psig, but not at the higher pressures. An increase

Figure 12: Lower limit of flammability of NPN as a function of pressure. (Reproduced and modified from [196].)

in the temperature to 443 K (170 °C) resulted in an apparent increase in the lower limit value because of the slow oxidation of NPN.

Obviously one would not want to use air to pressurize a propyl nitrate tank, but even using nitrogen instead of air carries some hazards; the temperature boundary of autoignition is shifted upward, as shown in Figure 13, but the nitrogen/NPN va-

Figure 13: Minimum spontaneous ignition and decomposition temperatures of NPN as a function of pressure. (Reproduced and modified from [196].)

por mixture can still decompose. The data given in this figure exhibit a behavior that is typical of that found with other combustibles at elevated pressures; the minimum spontaneous ignition temperature first decreases with an initial increase in pressure and then increases as the pressure is increased still further.

4.4.3.2 Explosive Sensitivity of *n*-Propyl Nitrate

4.4.3.2.1 Mechanical Shock Sensitivity of *n*-Propyl Nitrate

NPN is shock sensitive and must be handled with the same precautions as a liquid explosive. There are several reports about accidents with NPN. The shock and adiabatic compression sensitivity of both propyl nitrates is dependent on the degree of saturation with dissolved gases. Completely degassed nitrate esters behave differently from those that are saturated with pressurant gas or even air at sea-level pressure.

Both NPN and IPN have often been used as calibration fluids for drop weight impact sensitivity apparatus. Because there are so many different drop weight impact apparatus in use (Picatinny, Olin-Technoproducts, BAM), it helps to display the results from different machines on a common denominator using the same test samples. Both NPN and IPN are easy to obtain, easy to purify, and relatively safe to handle in small quantities.

The addition of 10% by weight of ethylene oxide to NPN or to 2-methoxyethyl nitrate increased the 50% point for positive results in the drop weight sensitivity impact tester from a value of 20–22 cm (8–9 in.) to a value of about 1.27 m (50 in.), which was the upper energy limit of the apparatus [163]. Mixtures of ethylene oxide and NPN were stored for 3 months at 333 K (60 °C), and there were no signs of reaction between the two monopropellants, as indicated by the absence of change in the drop weight sensitivity or refractive index.

Experimental impact sensitivity data were obtained for NPN as the condensed phase with gas bubbles consisting of argon, helium, nitrogen, and Freon-12 by themselves and binary mixed gas systems: (helium/oxygen), (nitrogen/oxygen), (Freon-12/oxygen), and one ternary system: (Freon-12/helium/oxygen) [201, 202]. The experimental program was able to separate the effects of heat capacity ratio, thermal conductivity, and chemical reactivity of the gas bubble on the impact sensitivity. Based on a proposed theoretical model of initiation, the impact sensitivity of NPN was correlated with the thermal diffusivity of the entrapped gas bubble. The correlation correctly predicted that argon, nitrogen, and Freon-12 gas bubbles with high C_p/C_v would require energies above 92 kg-cm for initiation to occur.

4.4.3.2.2 Explosive Shock and Card Gap Sensitivity of *n*-Propyl Nitrate

In the card gap test with 0.050-in.-thick cardboard cards and a 20-g tetryl booster and with the sample confined in a 27-mm-ID steel pipe, the probability of 10 failures within 10 tests in NPN was 0.54 at 16 cards [153].

Determining the safety properties of NPN included tests for flash point, flammability limits in air, and shock sensitivity [39, 203, 204].

The sensitivity of NPN and other sensitive liquids to accidental explosion by shock or adiabatic compression can be reduced by sparging it with a low-gamma gas prior to use [205]. The low-gamma gas should have a gamma (C_p/C_v) value of 1.15 or less. To be effective, the solubility of the gas must be high enough to result in a solution that contains 1–2 mass-% of the gas. Examples of low-gamma gases and vapors are butane, propane, chloroform, diethyl ether, and dimethyl ether.

Ab initio methods were used to model the propyl nitrate molecule and predict its behavior under conditions of shock initiation. Calculations of the molecular structure of propyl nitrate using *ab initio* methods indicated that NO₂ radical concentrations will decay quickly [206]. After completing the computations, the delay time of shock ignition was determined experimentally using a spectrophotometric method, i.e., the earliest emergence of an intermediate product for the loaded propyl nitrate was determined with a spectrometer. The first product to emerge from propyl nitrate after shock ignition was always NO₂. The monochromator was adjusted to the 463-nm wavelength of NO₂ absorption, and the time of arrival for the shock wave was measured by pressure gauges. The delay time determined by the spectrophotometric method was closer than that determined using a photoelectric diode, whose peak wavelength of sensitivity is about 800 nm. The emergence times for O, NO₂, CO, C₂, CH, CO₂, and H₂O fragments and products were obtained after the shock wave entered into the propyl nitrate.

4.4.3.2.3 Bullet Impact Sensitivity of *n*-Propyl Nitrate

Although NPN was rarely ever used in military equipment and was always at risk of bullet impact in a battlefield situation, the bullet impact sensitivity of NPN was tested [207]. Tests were conducted to determine the effects of bullet impact on NPN contained in four- and six-quart thin-wall aluminum canisters and in drums. Seven types of ammunition were used: 30-caliber ball, 50-caliber ball, 20-mm ball, 20-mm armor-piercing incendiary, 20-mm high-explosive incendiary, 7162-mm tracer, and a 20-mm flechette. The review of high-speed film (2000 and 4000 frames per second) indicated that there were no detonations; however, the 20-mm high-explosive incendiary rounds initiated burns.

4.4.3.2.4 Adiabatic Compression Sensitivity of *n*-Propyl Nitrate

The adiabatic compression sensitivity of NPN was tested in an adiabatic compression sensitivity tester developed by Aerojet in comparison to that of NM, methylacetylene, and a mixture of 60% ethyl nitrate/40% propyl nitrate [208]. The apparatus consisted of a pneumatically driven piston rapidly compressing a gas bubble above a liquid propellant sample. In a few cases, the apparatus was also inverted, pushing the liquid upward into the gas (vapor) bubble. The sensitivity was expressed in terms of the piston kinetic energy divided by the size of the gas bubble, which is the slope of a straight line separating the go-no go areas in an x-y chart (Figure 14). The results are summarized in Table 23. NPN was one of the more sensitive samples in this series of tests.

Figure 14: Adiabatic compression sensitivity of NPN. (Republished and modified from [208], with permission from © 1959 American Institute of Aeronautics and Astronautics; permission conveyed through Copyright Clearance Center Inc.)

Table 23: Adiabatic compression sensitivity of NPN in comparison to other monopropellants.

Compound	Adiabatic compression sensitivity, kg-cm mL ⁻¹
Mixture of 60% ethyl nitrate/40% propyl nitrate	4.0 ± 0.8
<i>n</i> -Propyl nitrate	6.7 ± 1.2
Nitromethane	10.4 ± 1.7
Methylacetylene	86 ± 12

Data source: [208]

The compression ignition sensitivity of a 60/40 volume ratio mixture of ethyl and NPN was tested in an apparatus where the compression piston was hydraulically driven, enabling the operator to control the compression ratio and piston travel distance and velocity [209]. The phenomena occurring during compression were observed by high-speed cameras and pressure-time traces. Compression tests at three different piston velocities and different chamber attitudes (orientations) showed that, contrary to expectations, increases in piston velocity did not always lead to lower compression ratios to achieve ignition. Ignition was observed at the lowest

compression ratios for the vertical downward piston travel, even at the slowest of the three piston velocities tested. See also [210].

In another apparatus, a stroke compressor, a volume of gas was rapidly compressed by a piston driven by a larger piston under a predetermined initial pressure. At the end of a stroke the piston was locked in place, thus maintaining essentially constant volume and, hence, constant pressure, except for a pressure drop due to cooling by the walls. Light emission in case of ignition was detected by a photomultiplier tube that “looked” through the window and showed up as a brightening of the pressure trace. The time at which light is emitted can thus be found. At a compression ratio of 17:1, peak pressures in the range 4.8–5.5 MPa (700–800 psia) and peak temperatures 650–800 K and compression rates of 20000 atm/s were obtained, with compression times of 1–4 ms. With different bubble sizes, ignition of NPN occurred in six out of nine tests [211].

The importance of the type of gas present in gas bubbles entrained in alkyl nitrate monopropellants was already pointed out in previously cited references in the section on drop weight impact sensitivity [201, 202].

The results of adiabatic compression sensitivity testing for NM, nitroethane, and a propyl nitrate are shown in Table 24 [212]. The data in Table 24 show that the values of 50% fire point of NM and propyl nitrate are nearly identical to those previously determined at the US Bureau of Mines, marked with an asterisk. Additional calculations were made to determine energy/liquid volume and compression power and are shown in the last columns. Since the pressure rise in the test chamber was very rapid (10000–1000000 psi/s), the compression was nearly adiabatic and rapid temperature rise resulted. NPN was the most sensitive liquid of the three liquids tested, with the least energy required to initiate an explosion in 50% of the tests.

Table 24: Adiabatic compression initiation sensitivity at volume ratio of 25 ($T_{\max} = 1311 \text{ K} = 1900^\circ\text{F}$).

Material	50% fire point h	Impact energy		Energy/time	Energy/time per volume of compression	Energy per volume of compression
	cm	Joule	kg-cm	J/s	$\text{J s}^{-1} \text{ m}^{-3}$	J/m^3
Nitromethane	23 (24.2*)	11.28	1.15	948	524×10^6	6×10^6
Nitroethane	37	18.15	1.85	1925	1006×10^6	10×10^6
<i>n</i> -Propyl nitrate	4 (4*)	1.96	0.2	68	38×10^6	1×10^6

Data source: [212]

4.4.4 Detonation Performance of *n*-Propyl Nitrate

The detonation velocity of $n\text{-C}_3\text{H}_7\text{ONO}_2$ in the liquid phase is 4700 to 5100 m/s [199, 200].

4.5 Applications of *n*-Propyl Nitrate

In addition to its application as a gas generant in gas generators for aircraft starter motors or torpedo propellant, NPN has been considered as a fuel for air-fuel explosives. NPN dissolves readily in kerosene and other hydrocarbon fuels and can improve their ignition characteristics at low temperatures or high altitudes. It can be added to diesel fuel as a cetane number improver.

5 Isopropyl Nitrate

Isopropyl nitrate, also known as IPN, 2-propyl nitrate, *sec*-propyl nitrate, 2-propanol nitrate, Isonite; nitric acid 1-methylethyl ester; *i*-C₃H₇ONO₂, CAS RN [1712-64-7], is an isomer of NPN and a potential monopropellant of equal or even higher importance.

Similar to the preparation of NPN, IPN is prepared by nitrating isopropanol with mixed acid, but the process is more difficult with secondary alcohols than with primary alcohols. In one process, a mixture of isopropanol and urea was dropwise added to boiling nitric acid [160]. The use of sulfuric acid in the mixed acid can be avoided by nitrating the isopropanol with nitric acid at 373 K (100 °C) in the presence of urea and ammonium nitrate [213]. The yield of IPN thus obtained can be over 85% under the optimum reaction conditions. The purity of IPN can be over 98% based on the analysis of the product by GC. The book by Liu (2015) contains several pages that describe the IPN production process [10].

IPN and other alkyl nitrates can be synthesized by reaction of alkyl halides (iodides or bromides) with silver nitrate, but that is a very expensive process.

IPN and other alkyl nitrates can be dried by passing them through molecular sieves [214].

5.1 Physical Properties of Isopropyl Nitrate

The physical properties of IPN are summarized in Table 25. See also [39, 166, 167, 215].

5.1.1 Density of Isopropyl Nitrate

The density of IPN as a function of temperature in a range of 233 to 303 K (−40 to +30 °C) can be expressed by the equation

$$\rho = 1.065 - 1.25 \times 10^{-3}t$$

where ρ is the density in g/cm³ and t is the temperature in °C [217].

Table 25: Physical properties of IPN.

Property	SI units	Other units	References
Molecular mass	105.0926 g/mol	9.516 mol/kg	[73]
Freezing point	190.6 K	−82.5 °C	
Triple point	190.81	−82.34 °C	[73]
Boiling point	374.85 K	101.7 °C	
	373.7 K	100.6 °C	[73]
Density at 293 K	1.036 g/cm ³	1.036 g/cm ³	[74]
	1.043 g/cm ³	1.043 g/cm ³	[216]
Refractive index n_D^{20}	1.3882		[216]

5.1.2 Compressibility of Isopropyl Nitrate

For data on the compressibility of IPN, see also [168].

5.1.3 Velocity of Sound in Isopropyl Nitrate

The room temperature sound speed was measured as 1.10 mm/μs [218].

5.1.4 Vapor Pressure of Isopropyl Nitrate

The vapor pressure of IPN in the range 273–343 K can be calculated from an Antoine equation:

$$\log_{10} p_p = 3.54496 - [1018.568 / (T - 89.622)]$$

where p_v is the vapor pressure in bar and T is the temperature in kelvin. For a single data point, a vapor pressure of 5.065 kPa at 293 K was reported.

5.1.5 Viscosity of Isopropyl Nitrate

The viscosity of IPN is 0.66 cPs at 293 K. Other sources gave a viscosity of 6.6×10^{-4} Pa s, which is the same number, but in different units; see [219].

5.1.6 Surface Tension of Isopropyl Nitrate

The surface tension of IPN is 29.3×10^{-3} N/m; see [219].

5.1.7 Optical Properties of Isopropyl Nitrate

5.1.7.1 IR Spectra of Isopropyl Nitrate

IR spectra are useful in determining the molecular structure of IPN and to detect trace quantities in the atmosphere and in the air in work spaces at rocket test sites. IR spectra are a useful analytical tool to verify purity of IPN and to measure the rate of decomposition of IPN under various conditions of heating and illumination. Raman and IR spectra of IPN and isobutyl nitrate were used in combination with computational stud-

ies employing DFT to assign the vibrational transitions to their corresponding normal coordinates [220]. Like other alkyl nitrates, the frequency of the NO₂ symmetric stretch remained relatively unchanged while the asymmetric stretch shifted to a lower frequency with increasing α -carbon substitution. The mode assignments involving the photochemically relevant —ONO₂ chromophore agreed well with those from previous IR work. Raman depolarization ratios provided evidence that the condensed-phase, ground-state molecular structure of isobutyl nitrate is of C_s symmetry. In contrast, the minimum energy structure of IPN was predicted to contain a pronounced twist around the C—O bond relative to the C_s-symmetry structure that lies 10.9 kJ/mol (2.6 kcal/mol) higher in energy. The IR intensities of IPN absorption bands were consistent with the twisted geometry, demonstrating that this conformer is most likely favored in solution.

5.1.7.2 Raman Spectra of Isopropyl Nitrate

Absolute resonance Raman scattering cross sections for IPN dissolved in cyclohexane or acetonitrile were measured at excitation wavelengths spanning the strong π – π^* absorption located at ~200 nm [221]. Resonance enhancement was observed for seven vibrational coordinates, all involving the —ONO₂ chromophore, demonstrating that the photoinduced excited-state structural evolution is dominated by structural changes localized to the —ONO₂ group. The absorption and absolute resonance Raman cross sections were modeled using the time-dependent formalism for absorption and Raman scattering. This analysis demonstrated that the photoinitiated excited-state structural-relaxation dynamics were multi-dimensional, and consistent with N—O bond cleavage. This observation is consistent with N—O bond dissociation being the dominant photodissociation pathway for larger (e.g., three or more carbon atoms) alkyl nitrates.

5.1.7.3 Ultraviolet Spectra of Isopropyl Nitrate

Eight simple representative nitrate esters (methyl nitrate, ethyl nitrate, NPN, IPN, *n*-butyl nitrate, *tert*-butyl nitrate, benzyl nitrate, and phenylethyl nitrate) were investigated by the extended Hueckel molecular orbital (MO) method [222]. The UV spectra of this set of compounds were recorded in heptane solution and resolved into a number of component bands as suggested by the MO calculations. The charge distributions of these molecules were calculated by an iterative charge consistency method.

5.1.7.4 Microwave Spectra of Isopropyl Nitrate

Low-resolution microwave spectra of *n*-propyl, allyl, *n*-butyl, isopropyl, and 2-butyl nitrate revealed mixtures of conformational isomers that have been characterized and correlated with conformations observed earlier in ethyl nitrate [176]. Conformers of the three primary esters could be assigned to *anti* and *gauche* configurations about the NOCC torsional angle coupled with *gauche* or *anti* configurations for *n*-propyl and *n*-butyl nitrate. IPN exists in a *gauche* conformation. For each compound all of the observed conformers were approximately equally stable.

5.1.8 Thermodynamic Properties of Isopropyl Nitrate

Thermodynamic properties of IPN are summarized in Table 26. The heat of evaporation of IPN at 298 K is 38.8 kJ/mol = 9.27 kcal/mol, and at the NBP it is 35.0 kJ/mol = 8.36 kcal/mol [11].

Table 26: Thermodynamic properties of IPN.

Property	SI units	Other units	References

5.2 Chemical Properties of Isopropyl Nitrate

5.2.1 Thermal Decomposition of Isopropyl Nitrate

5.2.1.1 Slow Liquid-Phase Decomposition of Isopropyl Nitrate

The rates of decomposition of IPN were compared to those of secondary butyl nitrate, normal butyl nitrate, and EGMN [41].

IPN was decomposed in a closed reactor at temperatures below 500 K and pressures up to 40 kPa [224, 225]. The reaction was first order with respect to IPN, and the main products of the reaction were isopropyl nitrite, methyl nitrite, NM, acetaldehyde, acetone, nitrogen oxides, and carbon dioxide. The addition of nitric oxide to decomposing IPN caused isopropyl nitrite and nitrogen dioxide to form exclusively in the earliest stages of reaction, although it did not alter perceptibly the overall rate and ki-

netics of reaction. The mechanism of decomposition may be rationalized in terms of an initial fission of the O—N bond to yield an isopropoxyl radical and nitrogen dioxide. The isopropoxyl radical is able to decompose to a methyl radical and acetaldehyde. Each of these products then reacts further, in part to convert nitrogen dioxide to nitric oxide and then to form organic derivatives of nitric oxide. The overall behavior of the low-temperature decomposition of IPN resembled that of ethyl and NPNs rather than that of *tert*-butyl nitrate.

In a similar study, IPN was decomposed at pressures greater than 1.4 MPa and at temperatures in the range 1300–1550 K using two types of reactors [226, 227]. Reaction times were extended from a few milliseconds (in a combustion chamber flow reactor) to several minutes (in a closed bomb reactor). The products of decomposition were analyzed by MS and their concentrations compared with those calculated for thermodynamic equilibrium. The main products were H_2 , N_2 , CO , CO_2 , CH_4 , NO , and H_2O . Even at long reaction times not all the measured concentrations corresponded to calculated values; in particular, the experimental concentration of methane was higher and that of hydrogen lower than expected for thermodynamic equilibrium. This very slow approach to overall thermodynamic equilibrium was due to the endothermic decomposition of methane, which is slow at temperatures below 1500 K. Therefore, the burning temperature of IPN is greater than expected, and the solid carbon content of exhaust gases remained low. The usefulness of IPN as a monopropellant would be enhanced by these effects.

Most of the work was done on IPN instead of isopropyl nitrite, but isopropyl nitrite is an intermediate product of IPN decomposition. Therefore, its decomposition was examined in a separate test series, starting with isopropyl nitrite instead of IPN. The rate of decomposition of isopropyl nitrite in dilution with CF_4 was studied in a static system over a temperature range of 403–433 K (130–160 °C) [228]. The addition of large amounts of NO (~0.9 atm) in place of CF_4 almost completely suppressed acetaldehyde formation. In addition to acetaldehyde, acetone and isopropyl alcohol were produced in approximately equal amounts. This test was part of a series of tests that also examined ethyl nitrite and *tert*-butyl nitrite.

The pyrolysis of IPN in the presence of NO was studied in a flow system with a molecular beam mass spectrometer at temperatures up to 700 K and pressures of 200–300 mbar, with residence times in the hot zone of the quartz reactor of ca. 30 ms [229]. This method allowed rapid quenching of the reaction and direct sampling and was designed to optimize detection of intermediates and radicals. Nitric oxide, NO , was added in the reactor at a partial pressure of 5–10 mbar to see whether it would impede the reaction. Isopropyl nitrite was shown to be a stable intermediate up to 490 K. From this molecule, several other species are formed by dissociation or reaction with methyl radicals and NO , and the alkyl nitrate reactions are thus similar to the alkyl nitrite reactions. In previous studies of IPN pyrolysis reactions the products varied strongly with temperature. It was shown that this temperature variation was due to

the existence of thermally labile species like isopropyl nitrite and methyl nitrite. Nitrosomethane, CH_3NO , was found at intermediate temperatures, and HCN was found at temperatures above 600 K.

The reaction path of nitrate ester decomposition is dependent on pressure. Secondary nitrate esters shift their major decomposition pathway from homolysis of the $\text{O}-\text{NO}_2$ bond to elimination of HNO_3 in a pressure range of 0.4 to 0.8 GPa [230]. The elimination reaction resembled carboxylate ester pyrolysis with E_1 character.

The decomposition of IPN was examined by DSC, heat flux calorimetry (HFC), and accelerating rate calorimetry (ARC) measurements [231, 232]. Evaporation precedes decomposition. First, the ASTM DSC method using a hermetic aluminum pan having a lid with a laser-produced pin hole was used to determine the vapor pressure of IPN. Results calculated from an Antoine equation were in substantial agreement with those determined from DSC measurements. From the latter measurements the enthalpy of evaporation was determined to be $35.32 \pm 0.62 \text{ kJ/mol}$. Attempts to determine vapor pressures above about 0.8 MPa resulted in significant decomposition of IPN(G). The enthalpy change for decomposition in sealed glass systems was found to be $-3.43 \pm 0.09 \text{ kJ/g}$ and $-3.85 \pm 0.03 \text{ kJ/g}$, respectively, from DSC and HFC measurements on IPN(L) samples loaded in air. Slightly larger exotherms were observed for the HFC results in air than those in inert gas, suggesting some oxidation occurs. In contrast, no significant difference in the observed onset temperature of about 423 K (150°C) was observed for either the HFC or ARC results. From DSC measurements, an Arrhenius activation energy for decomposition of 1264 kJ/mol was found. These measurements were also conducted in sealed glass systems, and decomposition appeared to proceed primarily from the liquid phase.

The IR spectra of NPN and IPN were measured using FTIR and found to be very similar. The kinetic parameters of the thermal decomposition of the two nitrates obtained by DSC showed that the thermal stability of IPN was slightly lower than that of NPN, according to the rate constants at three different temperatures and the peak temperature of the thermal decomposition [233].

Aluminized IPN may be used as a fuel-air explosive. Two mixtures of IPN and aluminum (mass ratio of IPN:aluminum = 2:1 and 1:13.7) were prepared, and their decomposition behaviors were determined by DSC [234]. The results showed that the most probable decomposition mechanism of the aluminized IPN did not change with a different ratio of components. The peak temperatures of the decomposition processes for the two samples were lower than that of pure IPN, and the apparent activation energy and the preexponential factor were correspondingly smaller. The thermal parameters and decomposition rate of the sample with an IPN:aluminum mass ratio of 1:13.7 were higher than those of the sample with a mass ratio of 2:1 during the whole process. See also [235].

5.2.1.2 Slow Vapor-Phase Decomposition of Isopropyl Nitrate

If IPN vapor is admitted to a heated quartz vessel at low pressures, chemiluminescence, similar to that observed with methyl nitrate, can be seen in a darkened room for less than a second. Depending on the sample pressure, it may precede an explosion of the vapor [236]. An examination of IPN over the temperature range 513–613 K (240–340 °C) and pressure range 13–1732 Pa (0.1–12 mm Hg) in a 350-mL quartz reaction vessel with a surface-to-volume ratio of 1.0 cm⁻¹ showed behavior similar to that of methyl nitrate. There were two modes of reaction: at low temperature and pressure in the aforementioned ranges the reaction was accompanied by an immediate (0.5 s) faint blue-white luminescence, while at higher pressures but the same temperature the luminescence was followed by a short induction period and then explosion. The two decomposition modes were not shown by NPN. Above 553 K (280 °C) and above the critical pressure, decomposition was accompanied by an immediate faint, brief, white glow.

A generalized gradient approximation of DFT was used to investigate the adsorption and dissociation of a single IPN molecule on an Al(111) surface [237]. Computations indicated that the IPN molecule tends to adsorb in a parallel mode with respect to the Al(111) surface. The dissociation behaviors and mechanisms of IPN on a metallic aluminum surface would be different from that on a catalyst like Cr₂O₃ or NiO.

5.2.1.3 Rapid Vapor-Phase Decomposition of Isopropyl Nitrate

The thermal decomposition of IPN vapor was studied in a shock tube in the temperature range 533–635 K [238]. A similar method was previously used for the study of the decomposition of di-*tert*-butyl peroxide. The kinetic rate equation was

$$k = 10^{16.51 \pm 0.55} \exp[-169.5 \pm 6 \text{ kJ/mol}/RT] \text{ s}^{-1}$$

Reactions in the vapor-phase decomposition of IPN as a candidate liquid gun propellant were studied by time-resolved monitoring using IR spectroscopy, identifying intermediates and developing kinetic rate equations for IPN decomposition [239].

The evaporation and chemical decomposition kinetics of single IPN droplets were investigated at 473, 498, and 523 K (200, 225, and 250 °C) by monitoring the gas phase using rapid-scan FTIR spectroscopy [240, 241]. The study used a reaction cell that could withstand pressures up to 10 bar and could be kept at a constant temperature (± 1 °C) in the interval 293–548 K (20–275 °C). The liquid was introduced into the chamber by a septumless injection system. The injected volume was variable between 0.2 and 10 μL . The cell volume was 8.9 cm³ and the optical path length was 5.0 cm. The cell was equipped with IR-transparent CaF₂ windows. For IPN, a nitrate symmetric stretching band centered at 1281 cm⁻¹ was selected and the boundaries for integration were set at 1279 and 1283 cm⁻¹. The temporal resolution used throughout the experiment was 0.25 s at a spectral resolution of 4 cm⁻¹. The droplet diameter was determined by recording the injection process and the formation of the droplet in the gas phase of the

Figure 15: Kinetic rate constants for IPN decomposition. (Republished and modified from [240], with permission of © 1989 Elsevier Science Technology Journals; permission conveyed through Copyright Clearance Center Inc.)

cell using a video, and measured diameters ranged from 1.9 to 0.5 mm, depending on the injected volume. The resultant activation energy determined from the slope of the solid straight line in an Arrhenius graph (Figure 15) was 158 kJ/mol and the frequency factor, $\log z$, was 15.2. These values compared quite well with those obtained by Julien et al. [238] in a shock tube experiment at 533–633 K (260–360 °C) with activation energy being 169.5 kJ/mol and the log of the frequency factor being 16.5. The corresponding values for other nitrate esters having related structures were 154.5 kJ/mol and 14.7 for NPN and 154.5 kJ/mol and 14.7 for ethyl nitrate (from [142]). Evaporation and decomposition rates were determined by a fit of a special model to the experimental absorption-time profiles. The model combined elements of quasi-static theory and simple chemical reaction kinetics.

The rapid decomposition of IPN and other alkyl nitrates in shock waves is a good method to obtain kinetic rate data for fast decomposition rates of alkyl nitrates [94]. The strand burning of liquid IPN and IPN mixtures will be discussed in *Encyclopedia of Monopropellants*.

5.2.2 Electron Bombardment Decomposition of Isopropyl Nitrate

Alkyl nitrates that need to be analyzed by MS need to be ionized by electron bombardment. Electron bombardment also offers clues about the weak links in a molecule where decomposition is likely to start first. The appearance potential is the electron energy level (in eV), where fragments begin to appear in the analyzer.

5.2.3 Photolysis of Isopropyl Nitrate

The photolysis of IPN and other alkyl nitrates is discussed in this chapter because this is a method for controlled ignition of the decomposition reaction in rocket engines by laser photolysis.

A comparison of the unimolecular decomposition behavior of electronically excited nitro-containing molecules with different $X-\text{NO}_2$ ($X = \text{C}, \text{N}, \text{O}$) bond connections is important for the understanding of the reactivity differences between NM, dimethylnitramine (DMNA), and IPN [242]. Illumination by UV lasers at different wavelengths, such as 226, 236, and 193 nm, created the excited states of these molecules. The decomposition products were then detected by resonance-enhanced two-photon ionization (R2PI), laser-induced fluorescence (LIF) techniques, or single-photon ionization at 10.5 eV. NO molecules were observed to be the major decomposition product from electronically excited NM, DMNA, or IPN. The NO products from decomposition of electronically excited (226 and 236 nm) NM and IPN displayed similar rotational (600 K) and vibrational distributions. OH radicals were observed as a minor dissociation product from all three compounds. The major decomposition pathway of electronically excited NM and IPN involved fission of the $X-\text{NO}_2$ bond to form electronically excited NO_2 product, which further dissociated to generate NO.

5.2.4 Analysis of Isopropyl Nitrate

The European NATO specification [243] for IPN, also known under the designation AVPIN, requires the purity properties listed in Table 27. There does not appear to be a US equivalent specification for IPN in the MIL-SPEC or MIL-PRF series.

Table 27: IPN specification NATOS-746AVPIN; Def Stan91-89/1.

UN designation	UN1222
Density at 20 °C	1041–1047 kg/m ³
Acidity, total, as nitric acid, max.	100 mg/L
Nitrite, as nitrous add, max.	25 mg/L
Water, max.	1200 mg/L

IPN and other alkyl nitrates may be used as cetane number improvers in diesel fuels. There are several analytical method for determining IPN in diesel fuels. IPN and other alkyl nitrates may be used as ignition enhancers in hydrocarbon fuels for pulse detonation engines.

5.3 Handling of Isopropyl Nitrate

When military propellant storage magazines in Russia were decommissioned as part of the SALT agreements, it was found that IPN had been used and stored in Russia and USSR member states under the code names OT-155 or Isonite. In one location in Azerbaijan, a stash of 24489 kg of OT-155 was found and had to be neutralized [244].

5.4 Safety Properties of Isopropyl Nitrate

5.4.1 Autoignition Temperature of Isopropyl Nitrate

The AIT of IPN vapor in air is 463 K (190 °C). The pressure-temperature conditions for the spontaneous ignition of IPN vapor were measured at 492–512 K [245]. Ignition was impossible below 492 K, even with increased pressure. Beyond 510 K the critical pressure fell below 0.8 kPa and did not vary much with further increases in temperature. The extent of self-heating preceding ignition (i.e., during the induction period) was limited (ΔT 20 K). The measured temperature excursions during ignition itself did not significantly exceed 200 K. The final products of ignition at 500 K included CH₄, methanol, acetaldehyde, and NM in substantial yield.

5.4.2 Flash Point of Isopropyl Nitrate

The flash point of IPN as measured with the Cleveland open-cup method is 295.3 K (22.2 °C).

5.4.3 Flammable Range of Isopropyl Nitrate in Air

USBM Bulletin 627 [196] and USBM Bulletin 503 [152] do not contain information on the flammable range of IPN (but they do contain data on NPN). One must assume that the upper limit of flammability is at 100% because no additional oxygen is needed to sustain combustion of IPN vapors. See also [246].

5.4.4 Detonation Sensitivity of Isopropyl Nitrate

IPN, like all other alkyl nitrates, is a potential explosive, and detonation can be initiated accidentally or deliberately by a variety of different stimuli. The hazard properties must be known to assign the proper transportation hazard classification for this chemical. The UN Transportation hazard code is UN 1222.

5.4.4.1 Cap Sensitivity of Isopropyl Nitrate

Shock initiation of detonation and critical diameters were investigated for IPN [247]. Both direct initiation of detonation and shock-to-detonation transition via the onset of detonation were observed. The initial shock pressure vs. time of onset of detonation

and catch-up time were measured, and the critical shock initiation pressure was determined to be in the range of 7–8.5 GPa at $0 \pm 5^\circ\text{C}$. The critical diameter for neat IPN was found to exceed 310 mm at 289 K (16°C) when confined in low-impedance PVC tubes. Shock initiation studies of IPN were carried out for four PVC attenuator thicknesses (6.24, 12.48, 18.72, and 25 mm) for a temperature range between 268 and 278 K (-5 and $+5^\circ\text{C}$). The critical gap thickness for shock initiation at $0 \pm 5^\circ\text{C}$ must be in a range of 18.72 to 25 mm. Aluminum particles of 100 nm average size were added to IPN in the belief that the fine aluminum would react within the reaction zone of the IPN detonation. The critical diameter of aluminized IPN indeed was found to lie between 29 mm (no detonation) and 48 mm (detonation) in PVC tubes, meaning it was one order of magnitude smaller than for neat IPN. The critical diameter for IPN detonation in the low-impedance PVC tube was larger than 307 mm. When compared with the critical diameter for NM detonation in a glass tube (20–25 mm), the critical diameter for IPN was one order of magnitude larger than that for NM.

5.4.4.2 Drop Weight Impact Sensitivity of Isopropyl Nitrate

The drop weight impact sensitivity of IPN has been measured by many laboratories. Because IPN is readily available, IPN was often chosen as a reference material when other sensitive materials were tested in the same apparatus.

The drop weight sensitivity of IPN was tested in comparison to NOSET-A and Otto Fuel II [248]. The results from instrumented drop weight tests indicated that ignition occurred at critical pressure ratios of 15 ± 1 for IPN, 124 ± 6 for Otto Fuel II, and 143 ± 6 for NOSET-A. The compressive energies for the ignition were 5, 12.2, and $13.1 \text{ kg cm cm}^{-3}$, respectively. NOSET-A and Otto Fuel II were respectively 2.6 and 2.4 times less sensitive than IPN.

5.4.4.3 Adiabatic Compression Sensitivity of Isopropyl Nitrate

The sensitivity of IPN and other monopropellants to accidental adiabatic compression ignition can be reduced by modifying the composition of the bubble so that the constituent gas in the bubble has a high specific heat and contains no oxygen. Various additives were tested to reduce the sensitivity of IPN to adiabatic compression, a property often called *dieseling*. For a vapor bubble above IPN that is saturated with propane, adiabatic compression ignition did not occur, even at the highest pressure ratios envisaged for any practical application [249]. Ignition has not been observed in any test with propane/IPN bubbles. The effect of dissolved propane on performance is insignificant, and there is no visible soot in the decomposition products. It was recommended that IPN tanks be filled with IPN saturated with propane. If desired, the initial pressure in the tank may be increased by the addition of nitrogen. For tanks that will never be used at above 303 K (30°C), it is sufficient to fill the ullage with nitrogen only.

Rapid compression of IPN vapor by a solid piston in a cylinder, even when it is in more than 50-fold dilution in air, can result in explosions [250, 251]. The

compression ratio ($V_{\text{initial}}/V_{\text{final}}$) was 11.4:1, and the travel duration of the piston was 20 ms. Pressure-time curves were measured and mean gas temperatures calculated from them. Product compositions and extents of reaction were measured by GC following removal of a sample and quenching by a rapid sampling technique. Heating accompanies rapid compression of gases, and its extent depends on the ratio of the specific heats, the adiabatic coefficient. Temperatures achieved at the end of compression in this apparatus by inert gases starting at room temperature fell in the range of ca. 500 K (for CO_2) to ca. 1000 K (for Ar). The temperature began to fall immediately after compression ceased. From starting pressures of about 45 kPa the range of maximum measured pressures attained was approximately 0.5–1.2 MPa. When IPN vapor (1 mol-%) is present in inert atmospheres, pyrolysis will occur and its extent will depend on the temperature achieved. For temperatures greater than 600 K, decomposition of IPN began before piston motion ceased, and more than 90% was consumed within about 5 ms. Even so, not all the IPN decomposed; a small fraction, which had resided in the cool boundary layers, remained in the end gas. Although pyrolysis in inert atmospheres is exothermic, ignition did not occur with inert gas dilution. When IPN vapor was compressed in the presence of oxygen (e.g., in air), the reaction occurring before the end of compression was followed by a second very exothermic stage. The temperature rose sharply, and ignition was achieved. Measured composition-time profiles showed that ignition resulted principally from the oxidation of aldehydes formed in the earlier stages by IPN decomposition and partial oxidation of its initial products.

In a continuation of this work the compression ratio ($V_{\text{initial}}/V_{\text{final}}$) was 10.8:1 and the time for motion of the piston was 20 ms [252]. Pressure-time histories were measured by pressure transducers and gas temperatures derived from them, assuming adiabatic compression. The temperatures reached during compression depended on the ratio of the principal specific heats of the reactant compositions; they fell in a range of around 500 K (in CO_2) to around 1000 K (in Ar). From starting pressures of about 0.5 atm the pressures reached varied between approximately 7 and 16 atm. Spontaneous ignition may be achieved in particular in the presence of oxygen, which was a prerequisite for the ignition of IPN vapor. Overall extents of reaction and product abundances were measured by GC and enthalpies of reaction calculated from these. At all but the lowest temperatures (600 K) virtually all of the IPN reacted (i.e., less than 5% remained), whether or not oxygen was present. But even at very high temperatures (1000 K) very small amounts always remained. This was attributed to the fact that part of the IPN was confined to a cool boundary layer at the combustion chamber wall. Pyrolysis of IPN occurred in inert atmospheres and among the major products at moderate temperatures were aldehydes, NM, methyl nitrite, and methanol. At temperatures above 1000 K, carbon monoxide and methane predominated. When excess oxygen was present, carbon oxides and formaldehyde were the predominant carbon-containing products.

In the adiabatic compression apparatus, temperatures rose to ~ 600 K at the end of the compression stroke. Conditions then remained constant for nearly a hundredth of a second, and 90% of the IPN has been consumed by the end of 8 ms. Dynamic absorption spectra showed that NO_2 was an important intermediate product during this period, although it was wholly consumed [253].

The adiabatic compression sensitivity of IPN, NOSET-A, and Otto Fuel II was measured at ambient temperature (290 ± 5 K = 17 ± 5 °C), also in comparison to drop weight sensitivity measured during the same investigation [248]. The adiabatic compression test apparatus consisted of a 28-mm-ID steel tube with 2.5-mm wall thickness bent in the form of a U at the lower end and containing a known volume of liquid (385 mL). This slug of liquid was accelerated into a closed volume (130 mL) by nitrogen gas pusher suddenly released from a pressurized reservoir of 2.65 L. Bubble and driver pressure were measured by fast-response quartz crystal transducers. The driver pressure was increased incrementally from one test to the next until dieseling was detected in the closed volume. For IPN, dieseling occurred at pressures above 24 bar, for Otto Fuel II dieseling occurred at pressures above 190 bar, and for NOSET-A dieseling occurred at pressures above 230 bar, which was near the measuring range of the pressure transducers. In all cases the reaction propagated into the liquid phase, but only with IPN was there evidence of a gas-phase ignition reaction. The U tubes were shattered into fragments.

5.5 Detonation Performance of Isopropyl Nitrate

5.5.1 Detonation Velocity of Isopropyl Nitrate

The velocity of sound of IPN was measured and used in the universal liquid Hugoniot to produce an estimated Hugoniot curve [218]. The room temperature sound speed for IPN was 1.10 mm/ μ s. Gas-gun-driven projectile impact, multiple-magnetic-gauge detonation pressure measurements were made to measure a Hugoniot state at 6 GPa, which was in good agreement with predictions. Two similar experiments were conducted at higher pressure inputs to study the shock-to-detonation transition in IPN. The high inputs required for initiation necessitated the use of a two-stage gun. One experiment with an input of 9.0 GPa into the IPN produced a run to detonation of about 3 mm, and the *in-situ* particle velocity profiles showed the expected homogeneous initiation behavior of a growing wave behind the shock front that overtook the front and decayed to a steady detonation. The reactive wave in the shocked IPN appeared to have achieved a steady superdetonation in both of the initiation experiments. The waveforms showed that the superdetonation achieved a velocity of about 8 mm/ μ s. After overtake of the initial wave, the overdriven velocity was 6.3 mm/ μ s, which then decreased to a steady 5.34 mm/ μ s. The measured steady-state detonation velocity was 5.34 mm/ μ s = 5340 m/s.

The detonation of liquid IPN depends on the type of confinement not only on the diameter of the tubes and their thickness, but also on the thermomechanical characteristics of the wall, i.e. its acoustical impedance relative to that of the liquid explosive. The detonation velocity of liquid IPN in steel tubes was between 5.3 and 5.4 mm/ μ s, depending on the tube diameter. The critical diameter in steel is about 10 mm radius (20 mm diameter) [254, 255]. Testing was done in 50-cm long tubes with varying wall thickness and internal diameters. Wall thickness was varied from 0.1 to 6 mm and internal diameter was varied from 10 to 42 mm. Initial temperature was varied from 270 to 350 K. The booster was a pellet containing 75% PETN in direct contact with the IPN. In a 27-mm tube, detonation velocity decreased from 5350 to 5100 m/s when the initial sample temperature was increased from 280 to 350 K. The limits of detonation depended strongly on the nature of the confinement. When IPN was contained in a lead tube at initial temperatures ranging between 310 and 325 K, the detonation velocity was found to be non-constant, decreasing roughly from 6000 to 5000 m/s along the length of the tube. However, in Pyrex and PVC tubes no detonation at all could be initiated in the range of experimental conditions, ($T \sim 330$ K, i. d. 42 mm). Experimental results lead to the conclusion that for charge diameters lower than critical diameters, the detonation of IPN is governed by the same physical principles as those governing detonation in gaseous mixtures. In particular, limits of detonation, density effect on the velocity of propagation and detonation pressure agreed both qualitatively and quantitatively with expected results deduced from the theories.

The detonation velocity and pressure of *iso*-PrNO₃ depends on the initial density ρ_1 of the liquid [256]. The detonation pressure increased linearly from $p_2 = 71$ kbar at $\rho_1 = 967$ kg/m³ and an initial temperature of $T_1 = 353$ K to $p_2 = 79$ kbar at $\rho_1 = 1042$ kg/m³ and $T_1 = 293$ K.

Confinement in heavy metal tubes has a pronounced effect on the detonability of IPN, also measured in comparison to that of NM [257]. Even the roughness of the inner surface of the wall can have an important effect on propagation of detonation waves in *iso*-PrNO₃.

Optical pyrometry was used to study initiation and propagation of detonation in homogeneous liquid high explosives (LHE): bis-(2-fluoro-2,2-dinitroethylformal), IPN and 1,6-diazido-2-acetoxylhexane [258]. The brightness temperature profiles were measured at various intensities of the incident shock wave. The observations showed that LHE decomposition progresses monotonically (particularly at low shock pressures) in time, and the intensity of the initial stage of detonation onset depends on the initial shock amplitude. Therefore the selection of the instant when the violent chemical reaction starts and, hence, of the adiabatic explosion delay is somewhat arbitrary.

5.5.2 Vapor Phase Detonation of Air/Isopropyl Nitrate Mixtures

There is interest in the potential use of IPN as a fuel or fuel additive for pulse detonation or rotating detonation propulsion. The detonation velocity of fine droplet/air mixtures is usually approximately 100–200 m/s slower than the calculated Chapman-Jouguet (C-J) velocity. Detonations of gaseous mixtures containing IPN were investigated in a 280 mm diameter, 7.3 m long detonation tube [259]. Measurements were made of detonation pressures, velocities and cell widths for a range of air/IPN mixtures. Cell widths were measured on soot-covered aluminum foil lining the chamber and plotted as a function of chamber pressure and equivalence ratio. Tests were conducted for stoichiometric air/IPN at initial pressures ranging from 10 to 100 kPa, and air/IPN equivalence ratios were varied between 0.3 and 3.0 for a series of tests at 1 bar initial temperature. To ensure full evaporation of the liquid fuel, tests were performed at an initial temperature of 373 K. Preliminary efforts were made to interpret the results using a detailed chemical reaction mechanism based on previous work on nitrated hydrocarbons, including propellants and high explosives. The reaction mechanism was compared with existing shock tube data and applied in a tentative investigation of the reaction zone structure. Measured detonation velocities (▼) did not vary from calculated velocities (solid line) by more than 3% (Figure 16).

Deflagration-to-detonation transition (DDT) in air/IPN mist aerosol sprays showed the formation of a self-sustained detonation wave, as indicated by the existence of a transverse wave and a spinning wave structure [219]. The run-up distance

Figure 16: Detonation velocity of IPN vapor as a function of fuel:air stoichiometric ratio. Comparison of measured detonation velocities with computed C-J velocities. (Reproduced and modified from [259], with permission from Dr. Josef E. Shepherd 11-Feb-2021.)

of the DDT process and the pitch size of the self-sustained spinning detonation wave in air/IPN mixtures were analyzed. A detonation wave formed during the DDT. Two propagation modes, a high-speed deflagration mode and a self-sustained detonation mode, of the shock-reaction complex in IPN mist/air mixtures were identified. The influence of the aerosol concentration and droplet size on the detonation propagation mechanism was studied. The minimum IPN concentration for DDT occurrence in air/IPN aerosol mixtures was 450 g/m^3 . The optimum IPN concentration for DDT occurrence was 473 g/m^3 . The propagation velocity and overpressure of the self-sustained detonation wave in air/IPN aerosol mixtures were measured and calculated. Under specific experimental conditions, a DDT process occurred in air/IPN aerosols within a transition distance of 14.35 m. A self-sustained detonation wave formed and propagated with velocities between 1540 and 1660 m/s, with a mean velocity of $\approx 1600 \text{ m/s}$. The overpressure of the detonation wave oscillated between 2.90 and 6.60 MPa, with a mean value of 4.75 MPa.

The explosion pressure, flame temperature, maximum rate of pressure rise, maximum rate of temperature rise, and LFLs were measured for two sets of IPN and mixed IPN/JP-10 in air aerosols at different concentrations and droplet mean diameters of 19 and $34 \mu\text{m}$ [260]. Experiments were performed to study various concentrations at various ignition energies for the IPN/air aerosols and the explosions of binary mixture aerosols with various mass ratios of IPN and JP-10. The results indicated that for the IPN/air and JP-10/air aerosols with a mean droplet diameter of $\sim 34 \mu\text{m}$, the maximum peak pressure and maximum peak temperature of the IPN/air aerosols were greater than those of the JP-10/air aerosols. The maximum rate of pressure rise of the IPN/air aerosols reached a maximum value of 395 MPa/s at a mean droplet diameter of $\sim 34 \mu\text{m}$, and the pressure increased more abruptly in the IPN/air aerosols than in the JP-10/air aerosols. The LFLs of the IPN/air aerosols occurred with a total concentration of 197 g/m^3 at a mean droplet diameter of $19 \mu\text{m}$ and a total concentration of 233 g/m^3 at a mean droplet diameter of $34 \mu\text{m}$.

5.6 Applications of Isopropyl Nitrate

IPN has been extensively investigated as a gas generant in auxiliary power units for jet aircraft [217]. Monopropellant applications of IPN will be discussed in *Encyclopedia of Monopropellants*. It has also been proposed as a power source for underwater vehicles and torpedoes [261].

As part of the Strategic Arms Limitation Talks (SALT) disarmament agreement, stocks of Isonite (IPN) stored in Azerbaijan (a former USSR republic) had to be demilitarized. It is not known what this material was used for and what they eventually did with it to neutralize it [262].

6 Higher Alkyl Mononitrates

Higher ($C_{n \geq 3}$) alkyl mononitrates would be too fuel-rich to be of any value as monopropellants. They may be used as process solvents or plasticizers. Amyl nitrate is used as a cetane number enhancer in diesel fuels.

6.1 *n*-Butyl Nitrate

There are three possible isomers of butyl nitrates, but they are rarely used as propellant ingredients. The physical properties of several butyl nitrates were already summarized earlier in Table 2.

Butyl nitrate, *n*-butyl nitrate, CAS RN [928-45-0], could not be made to explode under the maximum impact load of the apparatus used when tested for impact sensitivity in comparison to GTN, EGDN, and other energetic liquids [263].

The rates of decomposition of *n*-butyl nitrate were compared to those of IPN, *sec*-butyl nitrate, and EGMN [41].

6.2 2-Ethylhexyl Nitrate

2-Ethylhexyl nitrate, also known as EHN, 2-EHN, $CH_3(CH_2)_3CH(C_2H_5)CH_2ONO_2$, nitric acid 2-ethylhexyl ester, CAS RN [27247-96-7], is very useful as a plasticizer for hydroxyl-terminated polybutadiene (HTPB) propellants because it is completely miscible with the R45M prepolymer; not only that, it also solubilizes other plasticizer additives that will improve the mechanical properties of the cured propellant [264]. The solubilities of other plasticizers like GTN, BTTN, TMETN, and TEGDN in R45M are only on the order of one to two parts per hundred.

EHN is now widely used as an ignition enhancer and cetane number improver in diesel fuels. 2-EHN typically is used in a concentration range of 0.05 to 0.40 mass-% and may yield a 3 to 8 cetane number benefit. Other alkyl nitrates, as well as ether nitrates and some nitroso compounds, have also been found to be effective cetane number improvers, but they are not currently used commercially. The use of cetane number improver additives constitutes both a cost-effective and convenient way to accelerate startup, reduce emissions, and improve engine performance. As a result of this application, 2-EHN has become more widely available and can thus be used for rocket propulsion as well as automobile propulsion. The quantity of 2-EHN produced worldwide is now the largest quantity of any alkyl mononitrate currently in use. This explains the large number of recent publications on the thermal stability of EHN, apparently in response to some accidents that happened before mixing the material with diesel fuel.

6.2.1 Preparation of 2-Ethylhexyl Nitrate

Having identified in 1984 a growing demand for a nitrate ester diesel fuel Cetane Improver, the French company SNPE (Société nationale des poudres et explosifs) first began production of 2-EHN at its Sorgues production facility in France. When EURENCO was created in 2004 as an SNPE subsidiary, it was also entrusted with the development of this activity. Close to 30 years after it started, the production of Cetane Improver is a fully integrated and vital part of the Sorgues manufacturing complex. In November 2012, anticipating the growing need for fuel additives offering both technical and economic advantages, EURENCO launched a new subsidiary, VeryOne, to promote its 2-EHN solution, Cetane Improver, and meet the strong market demand worldwide [265].

2-EHN can be produced by nitration of iso-octanol with $\text{HNO}_3/\text{H}_2\text{SO}_4$ mixed acid. Before scaling up the production process, one must better understand the hazards involved with nitration reactions. DSC, ARC, and a reaction calorimeter were used to analyze the thermal stability of 2-EHN and the thermal hazard of iso-octanol nitration [266]. Four samples with different ratios of 2-EHN to mixed acid were tested using DSC. The results indicated that more mixed acid could catalyze the decomposition of 2-EHN. Three samples were tested using ARC, and the results showed that one sample started decomposing at the lowest onset temperature. This showed that there is a high probability of triggering the decomposition of the product 2-EHN from the iso-octanol nitration process. The overall heat generation of these reactions was large, even when keeping the temperature at 318–328 K (45–55 °C). This heat generation makes these semibatch processes difficult to control, especially on a pilot or plant scale. Based on the maximum temperature of the synthesis reaction, the only acceptable semibatch process is the nitration reaction at 283 K (+10 °C).

2-EHN can be made from nitric acid and 2-ethyl hexanol as raw materials and sulfuric acid as catalyst in a microchannel continuous flow reactor [267]. The best synthetic conditions were determined under experiments: 1:2 for the mol ratio of nitric acid and sulfuric acid; 1:1 for the mol ratio of nitric acid and 2-ethyl hexanol; the optimal liquid hourly space velocity obtained was 4000 h^{-1} . In this condition, the yield and purity of 2-EHN were relatively high. Experience gained in the production of 2-EHN can be applied to the production of other alkyl nitrates that are used as rocket propellant ingredients.

6.2.2 Physical Properties of 2-Ethylhexyl Nitrate

Physical properties of 2-EHN are summarized in Table 28.

Table 28: Physical properties of 2-EHN.

	SI units	Other units
Freezing point	228 K	−45 °C
Boiling point	373 K (decomp.)	100 °C (decomposes)
Vapor pressure	27 Pa @ 293 K	0.2 mm Hg @ 20 °C
Vapor pressure	40–53 Pa @ 313 K	0.3–0.4 mm Hg @ 40 °C
Vapor pressure	1.33 kPa @ 355 K	10 mm Hg @ 82 °C
Density	0.96 kg/dm ³ at 293 K	0.96 g/mL @ 20 °C
Kinematic viscosity	0.018 cm ² /s	1.8 cSt @ 20 °C
Solubility in water	12.6 mg/L @ 293 K	12.6 mg/L @ 20 °C
Heat of evaporation	368 kJ/kg	
Coefficient of thermal expansion		1.010 (between 10 and 20 °C at atmospheric pressure)

6.2.3 Chemical Properties of 2-Ethylhexyl Nitrate

6.2.3.1 Thermal Decomposition of 2-Ethylhexyl Nitrate

2-EHN is thermally unstable. When heated to above 373 K (100 °C), it may undergo a self-accelerating exothermic decomposition.

The thermal decomposition mechanism of 2-EHN, an additive to diesel fuel to improve the cetane number, was investigated in solution and in the gas phase [268]. In *trans*-decalin as a solvent the activation barrier for the thermal decomposition was 163 kJ/mol (39 kcal/mol). The decomposition at temperatures below 373 K (100 °C) was slow. Under high pressure conditions (2.4 kbar), the decomposition rates decreased, in accordance with what would be expected for a radical mechanism. Flash vacuum pyrolysis with subsequent detection of the products via MS or matrix IR spectroscopy identified NO₂, formaldehyde, and several olefins as the major decomposition products.

ARC was used to test the thermal sensitivity of four solid explosives and two liquid energetic materials, including PETN, RDX, HMX, TNT, nitroethane, and EHN [269]. Kinetic and thermodynamic parameters were calculated and analyzed. TMR_{ad} (time to maximum rate under adiabatic condition) was calculated. The thermal sensitivity of four solid energetic materials was decreasing in the order PETN RDX HMX TNT, which was consistent with results obtained using the traditional Wood's alloy bath method. The thermal sensitivity (sensitivity is the opposite of stability) ranking of six energetic materials from high to low was EHN PETN RDX HMX TNT NE.

The thermal decomposition of EHN in air was studied by microcalorimetry [270]. The effect of heating rate on the thermal decomposition of EHN was used to calculate the activation energy of thermal decomposition, TMR_{ad} (time to maximum rate under adiabatic condition) and the self-accelerating decomposition temperature. The results showed that a rise in the heating rate could shift the onset exothermic tem-

perature and peak temperature of EHN, but the reaction mechanisms were the same at all four temperature rise rates. The activation energy of thermal decomposition of EHN ranged from 144 to 214 kJ/mol. The self-accelerating decomposition temperature in typical storage containers was 348–371 K (75–98 °C).

2-EHN when mixed with acids becomes even more unstable. The thermal stability of EHN with concentrated acids under hot process conditions, four samples (pure EHN, concentrated sulfuric acid with EHN, concentrated nitric acid with EHN, and mixed acid with EHN) and three acids (sulfuric acid, nitric acid, and mixed acid) was measured by DSC and ARC [271]. The results indicated that concentrated sulfuric acid, concentrated nitric acid, and mixed acid can all reduce the onset of the exothermic decomposition temperature of EHN, especially concentrated sulfuric acid. DSC results also showed that the heat of EHN decomposition with nitric acid was greater than that of other samples. Based on ARC data, the kinetic parameters and T_{D24} (temperature at which time to maximum rate TMR_{ad} is 24 h) were calculated. The activation energy and T_{D24} of the EHN with acids, especially with concentrated sulfuric acid, were much lower than those of pure EHN. It was concluded that acids could decrease the stability of EHN and may be an important reason for frequent accidents.

2-EHN and nitrocellulose (NC) are commonly used energetic materials that have caused many thermal runaway reactions and explosions worldwide, and their thermal stabilities have always been an important issue. DSC was used to investigate the influence of thermal history during storage on the thermal stabilities of EHN and NC heated at different heating rates [272]. The decomposition kinetics of EHN and NC were determined by the Friedman isoconversional method. The kinetic parameters derived from heat balance were analyzed and used for the simulation of the time to the maximum heat release rate under adiabatic conditions (TMR_{ad}). The results indicated that the thermal history significantly influenced the dynamic DSC curves, decomposition kinetics, and thermal stability of NC, which decomposes autocatalytically, but the influence on EHN was negligible, whose decomposition proceeds according to an n th-order law.

2-EHN is unstable and has caused fire and explosion accidents. The mechanism of EHN thermal decomposition was investigated by DSC under non-isothermal and isothermal conditions, and its thermal decomposition kinetics was calculated [273]. A model for the decomposition reaction was established and verified by an isothermal method. The results indicated that the activation energy for EHN was 154 ± 3 kJ/mol under non-isothermal and 157 ± 7 kJ/mol under isothermal conditions. In addition, there was almost no difference in E_{act} at various extents of the reactant conversion, suggesting that a single-step reaction model is suitable to describe the decomposition reaction. In addition, the temperature of no return and self-accelerating decomposition temperature were calculated under non-isothermal and isothermal conditions. The kinetic parameters under the isothermal conditions were in good agreement with those obtained under the non-isothermal conditions.

6.2.3.2 Analysis of 2-Ethylhexyl Nitrate

Although 2-EHN is not used in liquid rocket propellants, methods for its analysis are listed here because the same methods can be used for the analysis of other alkyl nitrates: [274–276].

6.2.4 Safety Properties of 2-Ethylhexyl Nitrate

2-EHN had a low acute oral toxicity when tested in animals. The median lethal dose (LD50) was 5000 mg/kg (rat), and therefore 2-EHN was not classified as harmful or toxic if swallowed (under OSHA guidelines). The inhalation exposure guideline for 2-EHN is 1 ppm based on an 8-h time weighted average (TWA). In light of the potential temporary effects of overexposure, it was suggested that 1 ppm should also be adopted as reference standard for short-term exposures averaged over 15 min (STEL).

2-EHN is a combustible liquid but is not classified as a flammable liquid. The closed-cup flash point of 2-EHN is above 343 K (70 °C).

2-EHN was found to be biodegradable by microbial communities from refinery wastewater treatment plants but was recalcitrant to those of urban wastewater treatment facilities [277]. Out of 18 hydrocarbon-polluted or non-polluted soil samples, 6 microbial populations were also able to degrade 2-EHN.

7 Alkyl Nitrates with Ring Structures

7.1 Glycidyl Nitrate

Glycidyl nitrate (GLYN) is a monomer that can be polymerized to a solid energetic binder polyGLYN or can be oligomerized to form lower-molecular-mass oily liquids suitable as energetic plasticizers.

7.1.1 Preparation of Glycidyl Nitrate

The preparation of GLYN by the nitration of glycidol with dinitrogen pentoxide must be carried out at low temperatures and is usually completed within a few seconds:

Higher temperatures and extended nitration times lead to unwanted ring opening:

GLYN dimer plasticizer can be used for plasticization of polyether binder systems, such as polyGLYN and polyNIMMO [278]. It can be prepared by end-capping a 1,4-butanediol spacer unit with GLYN and then nitrating the terminal hydroxyl groups [279, 280]. Nitration increased both oxygen balance and energy content and prevented unwanted reaction of plasticizer with isocyanate crosslinking agent in polyurethanes. It is normally a mixture of oligomers that has a low T_g and low impact sensitivity compared with nitrate esters such as BTTN and TMETN:

Synthesis of GlyN Dimer

As with the 3-nitratomethyl-3-methyloxetane (NIMMO) oligomer, nitration both increases oxygen balance and energy content and prevents unwanted reaction of the plasticizer with the isocyanate crosslinking agent. GLYN dimer is normally a mixture of oligomers and has a low T_g ($208.2\text{ K} = -64.9^\circ\text{C}$) and impact sensitivity compared with conventional nitrate esters such as BTTN and TMETN.

The traditional method synthesizing GLYN is the partial nitration of glycerol to 1,3-dinitroglycerol, which does not have to be isolated but can be first separated from excess acid, neutralized, and then reacted with sodium hydroxide to achieve the epoxide ring closure [281].

The yield of GLYN from chloro-epoxypropane and diluted nitric acid can be increased in the presence of 5-aminotetrazolium nitrate [282]. The presence of 5-aminotetrazolium nitrate as catalyst and conitrating agent enabled GLYN to be produced smoothly and in excellent yield under mild condition, increasing the yield from 66 to 81%. The product was characterized by FTIR and ^1H NMR spectroscopy.

7.1.2 Physical Properties of Glycidyl Nitrate

The physical properties of GLYN dimer are listed in Table 29.

Table 29: GLYN dimer properties.

	SI units	Other units
Glass transition temperature, T_g	208.2 K	-64.9 °C
Density, dimer	1.38 kg/dm ³	1.38 g/cm ³
Density, monomer	1.332 g/cm ³	
Drop weight sensitivity, 50% H		18.1 cm
Autoignition temperature	440 K	167 °C
Detonation velocity	6900 m/s	
Detonation pressure, P_{C-J}	17.7 GPa	
Enthalpy of formation ΔH_f	-789 kJ/mol	-188.6 kcal/mol

7.1.2.1 Molecular Structure of Glycidyl Nitrate

Oligo-GLYN plasticizer offers a number of advantages over traditional nitrate ester plasticizers (TEGDN, TMETN, BTTN) like excellent miscibility with normal-molecular-weight polyGLYN, low volatility, low T_g as compared to normal-molecular-weight polyGLYN, decreased plasticizer mobility, and excellent enthalpies of combustion and explosion characteristics.

The linear GLYN dimer molecule is significantly smaller than polyGLYN and is prepared by end-capping a 1,4-butanediol spacer unit with GLYN and then nitrating the terminal hydroxyl groups [283]. Applications of GLYN polymers as binders in solid propellants will be discussed in future volumes of this series of encyclopedias.

7.2 Oxetane Plasticizers. 3-Nitratomethyl-3-methyloxetane

3-Nitratomethyl-3-methyloxetane (NIMMO) is a monomer that can be polymerized to form a high-energy solid propellant binder (polyNIMMO) or oligomerized to form a lower-molecular-mass oily liquid that can be used as a plasticizer.

Linear NIMMO oligomer

Oxetane plasticizers are linear nitratomethyl(methyl)oxetane (NIMMO) oligomers. Linear NIMMO oligomers (consisting of a chain of 1–10 monomers) have lower T_g than the cyclic NIMMO. The most promising energetic plasticizers for use with nitro-substituted polyethers appear to be NIMMO oligomer and GLYN dimer. Linear NIMMO oligomers (1–10 monomer units) are used as plasticizers in polyNIMMO binder systems. To remove the terminal hydroxyl groups and prevent unwanted reaction with the isocyanate crosslinking agent, oligomeric NIMMO has been further nitrated, which also increased the oxygen balance and energy of binder system. This is similar to what had been done with oligomeric GLYN:

7.3 Bridged and Caged Hydrocarbon Nitrates

7.3.1 Cubyl Nitrates

Cubyl nitrates can also be called nitroxycubanes. Similar to nitrocubanes, these are expected to be highly energetic compounds, suitable as explosives and propellants.

The previous chapter on nitro compounds included a section on polynitrocubanes. Along the same track of development, polynitroxycubanes have been studied, although for the time being only by computer. A series of nitroxycubanes, in which the hydrogen atoms on cubane have been progressively substituted for nitrate groups, were studied by computations to predict optimized geometries, vibrational frequencies, enthalpies of formation, and enthalpies of combustion [284]. The results indicated that the enthalpies of formation decreased as the number of nitrate groups increased, which is in direct opposition to what calculations have shown occurs for both the nitroso and the nitrocubane series. Given the difficulty in synthesis of octanitrocubane, octanitroxycubane may still be a more viable candidate for use as a new potential high-energy material once we figure out how to make it.

7.3.2 Adamantyl Nitrates

In parallel with synthesizing nitroadamantane and polynitroadamantanes, efforts have started to prepare adamantyl nitrate and adamantyl polynitrates and evaluate them as energetic materials.

The heats of combustion and enthalpies of evaporation for adamantyl nitrate and adamantandiyil dinitrate were measured by precision calorimetry methods [285]. On the basis of these data, the enthalpies of formation in the standard state and in the gas phase were calculated.

In a similar effort, the heats of formation for 26 adamantyl nitrates were calculated and it was found that the heats of formation of the 26 isomers with the same number of $-\text{ONO}_2$ groups (n) were not correlated well with the corresponding substituted positions [286]. According to the obtained heats of detonation, detonation velocities, and detonation pressures using the Kamlet-Jacobs equations, it was found that when $n = 7\sim 8$, the adamantyl nitrates meet the criterion as high-energy-density compounds. The calculations on BDEs of $\text{N}-\text{O}$ showed that the adamantyl nitrates with geminal ONO_2 groups always had the worst stability among the isomers, and all the adamantyl nitrates with geminal ONO_2 groups had similar stability. Considering the stability requirement, only 1,2,4,6,8,9,10-adamantyl heptanitate was recommended as a feasible high-energy-density compound. *Ab initio* calculations of the electronic structure showed that the $\text{O}-\text{NO}_2$ bond is the trigger bond during thermolysis, which agreed with the result derived from the study of dissociation energies of $\text{N}-\text{O}$ bonds.

8 Higher Alkyl Polynitrates

Alkyl nitrates containing more than one carbon atom and containing more than one nitrate ester group are very energetic compounds and many of these compounds find applications as gun propellants, as rocket propellants, as energetic plasticizers for solid propellants, and eventually also as explosives by themselves. They were also

evaluated as liquid gun propellants. The best known member of this group is glycerol trinitrate (nitroglycerin, NG, GTN). Other examples are nitrocellulose, EGDN, and PETN.

Nitrocellulose can be softened by swelling (gelatinizing) it with GTN, creating extrudable double-base propellants. A large portion of solid propellant literature is dedicated to physical methods of processing (mixing, casting, extruding) that have very little to do with chemistry. Therefore, we are not attempting to include all the details of nitrate ester processing in this book. Also, there are thousands of patents covering these types of double base propellants with and without various performance or processing-improving additives which we chose to ignore.

Energetic plasticizers for double-base propellants, composite-modified double-base propellants, or composite propellants will be discussed in future volumes of this *Encyclopedia of Rocket Propellants*. The following sections are arranged by increasing number of carbon atoms and increasing number of nitrate groups.

8.1 Higher C_n (n ≥ 2) Alkyl Polynitrates

Alkylene dinitrate compounds were prepared from alkane diols such as 1,6-hexane diol, 1,8-octane diol, 1,10-decane diol, and 2-methyl-2,4-pentane diol using conventional nitration reactions [287]. These dinitrate compounds were tested as cetane improver for diesel fuel. Results showed that the cetane number values had increased about 1 and 3 units for 0.05 and 0.10% by weight of dinitrate compounds, respectively, compared with base diesel fuel. Their efficiency was higher than that of a commercial cetane improver, 2-EHN.

9 C₂ Alkylpolynitrates

9.1 Ethylene Glycol Dinitrate

Ethylene glycol dinitrate, also known as C₂H₄N₂O₆, ethanediol dinitrate, 1,2-ethanediol dinitrate, EGDN, glycol dinitrate, dinitroglycol, nitroglycol, ethyleneglycol dinitrate, ethylene dinitrate, 1,2-dinitratoethane, 1,2-dinitroxyethane, 2,2-oxidiethyl dinitrate, CAS RN [628-96-6], is a viscous, pale yellow to colorless liquid explosive that can be used as a plasticizer for double-base propellants:

It has a perfect oxygen balance of ±0% to oxidize all carbon to carbon dioxide and all hydrogen to water when it burns. It is thermally more stable and less sensitive to

impact than GTN. However, its vapor pressure is higher than that of GTN, and that limits the range of its applications.

It was once used as a freezing point depressant for GTN in low-freezing dynamites and as an energetic plasticizer for double-base propellants. A vast amount of information on EGDN has been collected and published in Fedoroff, *Encyclopedia of Explosives and Related Items*, Vol. 6, p. E259–E279.

Like all alkyl nitrates, EGDN can be prepared by nitration of ethylene glycol with mixed acid or dinitrogen pentoxide. EGDN can be prepared by reaction of ethylene with nitric acid, where a byproduct is 2-nitroethanol nitrate. It can also be prepared by bubbling ethylene gas through the anode space of an electrolyzed calcium nitrate/nitric acid solution.

9.1.1 Physical Properties of Ethylene Glycol Dinitrate

The physical properties of EGDN are summarized in Table 30. Additional physical properties of EGDN are summarized in [288–290].

Table 30: Physical properties of EGDN.

Property	SI units	Other units				References
Molecular mass	152.0630 g/mol	6.5762 mol/kg				[73]
Freezing point	253 K	−20 °C				[74]
	250.8 K	−22.3 °C (supercooling)				[291]
Boiling point	470 K dec.	387 °F dec.				
Density	1.4918 g/cm ³ at 293 K					[10]

ΔH_{298}^f	−233 kJ/mol	−1532 kJ/kg	−55.7 kcal/mol	−366.2 cal/g		[73]
Enthalpy of evaporation at 343–465 K	55.3 kJ/mol	363.7 kJ/kg	13.2 kcal/mol	86.9 cal/g		[73]

9.1.1.1 Physical-Mechanical Properties of Ethylene Glycol Dinitrate

Twenty determinations of the specific gravity of EGDN at temperatures ranging from 275.7 to 299.8 K (2.6–26.7 °C) were made and, when plotted, indicated a straight-line function from which the following values in Table 31 were read off at regular temperature intervals [291].

Table 31: Density of EGDN.

Temperature		Specific gravity, $x^\circ/15^\circ$, interpolated
K	°C	g/cm ³
273	0	1.5176
278	5	1.5105
283	10	1.5033
288	15	1.4962
293	20	1.4890
298	25	1.4817

Data source: [291]

Table 32 gives the vapor pressure of EGDN in comparison to that of GTN.

Table 32: Vapor pressure of EGDN in comparison to that of GTN.

Temperature, K	288	288	298	298	308	308	318	318	328	328

Ethylene glycol dinitrate	3.11	0.0233	9.41	0.0706	29.2	0.2189	59	0.4425	128	0.9619
Glycerol trinitrate	0.17	0.0013	0.24	0.0018	0.61	0.0046	1.72	0.0129	4.80	0.0359

Data source: [15]

The vapor pressure of glycol dinitrate as determined using the air-bubbling method, in which 19 L of air was passed through pure material at a fixed temperature and the loss in weight determined, was found to be 0.93 Pa (0.007 mm Hg) at 273 K (0 °C) and 7.53 Pa (0.0565 mm Hg) at 295 K (22 °C) (Table 33) [291].

EGDN, then, has a vapor pressure approximately 150 times 0.049 Pa (0.00037 mm Hg) at 295 K (22 °C) found for GTN.

Table 33: Vapor pressure of EGDN.

Temperature			Vapor pressure		
K	°C	°F	millibar	Pa	mm Hg
273	0	32	0.006	0.606	0.00456

353	80	176	7.8	787.8	5.928
373	100	212	29	2929	22.04

Data source: [291]

The vapor pressures of EGDN along with those of three solid nitroaromatics were measured by an electron-capture gas-chromatographic method in a temperature range of 240.15 to 298.15 K for EGDN [292]. The temperature dependence of the vapor pressure can be expressed by the equation

$$\log_{10} p = (10.55 \pm 0.08) - (3476 \pm 22)/T$$

where p is the vapor pressure in mm Hg and T is the temperature in kelvin. At one time, EGDN was added to GTN to lower the freezing point and because it was easier to produce from petroleum-derived feedstock (ethylene, ethylene glycol) than glycerol and its trinitrate. However, the increased vapor pressure made dynamite products containing this mixture more difficult to handle [293]. See also [294].

A comparison of vapor pressure data from six papers dealing with vapor pressure measurements of EGDN found that the data from these papers as illustrated in Figure 17 were in very good agreement but that the data from John [294] were not consistent with the rest and had to be excluded from the best fit to Clausius-Clapeyron equations [295]. EGDN melts at 250.8 K (−22.3 °C) and hence the data points at 240 and 243 K (−33 and −30 °C) were excluded. The Clausius-Clapeyron fit of the data for EGDN led to the equation

$$\log P = A - B/T = 10.537 - 3473/T$$

where P is the vapor pressure in mm Hg and T is the temperature in kelvin for the temperature range 251–323 K (−22 to +50 °C). The vapor pressure of EGDN at 298 K was extrapolated to be 7.63×10^{-2} mmHg. The heat of evaporation is 66.5 kJ/mol (15.89 kcal/mol).

EGDN is less viscous than GTN. The viscosity and fluidity of EGDN and GTN were compared on a side-by-side basis at 296 K (23 °C). The fluidity of water was arbitrarily set at 100 (Table 34).

The solubility of EGDN in water is 0.68 g/100 g water at 293 K and 0.92 g/100 g water at 323 K.

9.1.1.2 Optical Properties of Ethylene Glycol Dinitrate

The IR spectrum of EGDN is shown in Figure 18.

Figure 18: IR spectrum of liquid EGDN. (From [296].)

The MIL SPEC has a similar IR spectrum for EGDN, which contained 0.25% 2-nitrodiphenylamine (2-NDPA) as a stabilizer (Figure 19).

Figure 19: IR spectrum of liquid EGDN. (From MIL-E-48225.)

The IR spectrum of EGDN and six other dinitrate esters were computed by a DFT method. The actual, measured, and predicted, computed IR spectra of EGDN are compared in Figure 20 [297]. Note that the two parts of this figure have different abscissa scale expansions. There are five very strong IR active modes. One is in

Figure 20: Comparison of calculated (left) and experimental (right) IR spectra of EGDN. (Republished and modified from [37], with permission of © 2009 John Wiley Sons; permission conveyed through RightsLink.)

Note different abscissa scale expansions.

a range of $1682\text{--}1700\text{ cm}^{-1}$, corresponding to --NO_2 asymmetric stretching. Another is in the $1265\text{--}1295\text{ cm}^{-1}$ range, arising from --NO_2 symmetry stretching. The third is located in a range of $1125\text{--}1145\text{ cm}^{-1}$, corresponding to the characteristic peaks of ether groups ($\text{CH}_2\text{CH}_2\text{O}$). The fourth is in a range of $1002\text{--}1034\text{ cm}^{-1}$, corresponding to C—O symmetry stretching. The IR spectra can be used to calculate thermodynamic properties of EGDN vapor. Correlations were established to predict the detonation performance of di-, tri-, tetra-, penta-, and hexa-ethylene glycol dinitrate.

Figure 21: Comparison of IR spectra of three different EGDN samples. (Reproduced and modified from [298]; CEJEM; CC BY-NC-ND 3.0.)

The IR spectra of three different samples of EGDN prepared from ethylene glycol of different origins and different purities are compared in Figure 21 in an effort to support the quality control of this material before it is allowed to be worked into propellants.

For additional discussion of vibrational spectra and conformational composition of EGDN in solid phases, see [299]. EGDN is used as a taggant in some explosives because it is easily detected by its IR spectrum [300].

The refractive index of pure EGDN was measured at 25 points between 276.1 and 310.6 K (3.0 and 37.5 °C) using a water-jacketed refractometer and employing sodium D light. The values were plotted against temperature readings and found to represent a straight-line function. From this straight-line graph the values in Table 35 were interpolated at regular temperature intervals.

Table 35: Refractive index of EGDN with sodium light.

Temperature			Refractive index		
K	°C	n_D	K	°C	n_D
273	0	1.4546	293	20	1.4473
278	5	1.4528	298	25	1.4454
283	10	1.4509	303	30	1.4436
288	15	1.4491	308	35	1.4417

Data source: [291]

The refractive index with white light at 296.3 K (23.2 °C) was 1.4452. Table 36 is a comparison of the refractive indices of three nitrate esters at different temperatures.

Table 36: Refractive indices of nitrate esters.

Temperature, K	Temperature, °C	Glycerol trinitrate	Ethylene glycol dinitrate	Diethylene glycol dinitrate
288	15.0	1.4751	1.4491	1.4536
293	20.0	1.4732	1.4472	1.4517
298	25.0	1.4713	1.4454	1.4498
202	30.0	1.4693	1.4435	1.4479

9.1.1.3 Thermodynamic Properties of Ethylene Glycol Dinitrate

The heat of combustion of EGDN was measured in a calorimeter in comparison to that of GTN (Table 37). NIST recalculated the heat of combustion of EGDN as -1123.3 kJ/mol. The heat of evaporation is 55.3 kJ/mol at 358 K and 68.3 kJ/mol at 255 K.

Table 37: Heat of combustion of EGDN in comparison to that of GTN.

	At constant volume				At constant pressure			
	J/g	cal/g	kJ/mol	kcal/mol	J/g	cal/g	kJ/mol	kcal/mol
EGDN	7380	1763.9	1122	268.22	7332	1752.5	1115	266.48
GTN	6822	1630.4	1549	370.25	6787	1622.1	1541	368.36

Data source: [291]

The enthalpies of formation in Table 38 were obtained from these heats of combustion.

Table 38: Enthalpy of formation of EGDN in comparison to that of GTN.

Compound	Enthalpy of formation			
	J/g	cal/g	kJ/mol	kcal/mol
EGDN liquid	1529	365.5	233	55.580
GTN liquid	1505	359.8	342	81.7

Data source: [291]

The enthalpy of evaporation for EGDN is 66.5 ± 0.38 kJ/mol (15.9 ± 0.09 kcal/mol) as derived from vapor pressure measurements [292]. The heat of evaporation of EGDN reported by an earlier investigator [293] was 68.6 ± 0.5 kJ/mol (16.4 ± 0.13 kcal/mol). The enthalpy of formation of EGDN vapor is -45.3 kcal/mol.

The heat capacity, standard entropy, and standard enthalpy of EGDN vapor derived from IR spectra and statistical thermodynamic/quantum mechanical calculations as a function of temperature can be calculated from [297, 301]:

$$\begin{aligned}
 C_p &= 26.2633 + 0.4616T - 2.2428 \times 10^{-4}T^2 \\
 \Delta S &= 261.8054 + 0.5855T - 1.7774 \times 10^{-4}T^2 \\
 \Delta H &= -5.6124 + 0.0766T + 1.1842 \times 10^{-4}T^2
 \end{aligned}$$

where C_p is the molar heat capacity in $\text{J K}^{-1} \text{mol}^{-1}$, ΔS is the standard molar entropy $\text{J K}^{-1} \text{mol}^{-1}$, ΔH is the standard molar enthalpy in kJ/mol, and T is the temperature in kelvin. The standard molar enthalpy of formation of liquid EGDN is -238.66 kJ/mol. Similar data are available for DEGDN and TEGDN. Other data reported for the heat of combustion of EGDN are 1115 kJ/mol (266.5 kcal/mol) [302].

9.1.1.4 Molecular Structure of Ethylene Glycol Dinitrate

The molecular structure of EGDN is illustrated in Figure 22.

Figure 22: Molecular structure of EGDN.

9.1.2 Chemical Properties of Ethylene Glycol Dinitrate

Although EGDN gelatinizes nitrocellulose faster than GTN, it cannot be used in double-base propellants because its vapor pressure is too high.

9.1.2.1 Thermal Decomposition of Ethylene Glycol Dinitrate

Similar to methyl nitrate and ethyl nitrate being used as model compounds for the decomposition of other, more complex alkyl nitrates, the decomposition of EGDN has also been examined for more academic than practical reasons.

The molecular structure of EGDN and its mono ionic forms were examined by semiempirical and *ab initio*-type quantum chemical computations [303]. The computation revealed that the neutral and anionic forms are exothermic whereas the cation is endothermic. All of the systems were found to be stable, but the calculations indicated that plus and minus charge developments caused drastic geometrical changes in the molecular structures, resulting in bond elongation, possibly bond cleavage in the ester N—O bond.

A DFT method was used to study the geometric and electronic structures, thermodynamic properties, detonation performance, and pyrolysis mechanisms of six dinitrate esters including EGDN [297]. The IR spectra of these compounds were obtained, and the bands were assigned by vibrational analysis. The thermodynamic properties were evaluated based on the principle of statistic thermodynamics. Detonation performances were evaluated by Kamlet-Jacobs equations based on the calculated densities and heats of formation. For the nitrate esters, the O—NO₂ bond is a trigger bond during the thermolysis initiation process.

The activation energy of the thermal decomposition of EGDN in a DSC was 145.06 or 148.04 kJ/mol, depending on which method was used for data reduction [298]. See also [304].

9.1.2.2 Homogeneous Vapor-Phase Decomposition Mechanisms of Ethylene Glycol Dinitrate

Most of the work on ethylene glycol nitrates has been done on the dinitrate. Therefore, it is unusual to find studies on the thermal decomposition of ethylene glycol mononitrate [41].

9.1.2.3 Photolysis of Ethylene Glycol Dinitrate

Most studies on the photolysis of alkyl nitrates were done to investigate their role as a sink of nitrogen in the atmospheric nitrogen cycle and examined the alkyl mononitrates. Surprisingly, the polluted atmosphere may even contain alkylene dinitrates, such as those formed from ethylene or propylene and dinitrogen tetroxide.

9.1.2.4 Military Specifications for Ethylene Glycol Dinitrate

The purity requirements for EGDN for government applications are spelled out in MIL-E-48225 [305], listed in Table 39. That specification also contains recommended methods for analyzing EGDN for assays and contaminants.

Table 39: Specification requirements for EGDN.

Properties	Percent	Method
Nitrogen, minimum	18.06	4.4.1, Method 414.1 of MIL-STD-650
Moisture, maximum	0.25	4.4.2, Method 101.4 of MIL-STD-650
Acidity as nitric acid or alkalinity as sodium carbonate, maximum	0.01	4.4.3, Method 102.3 of MIL-STD-650
Stability, minutes, minimum	8.0	4.4.4

Data source: [305]

9.1.3 Toxicity of Ethylene Glycol Dinitrate

EGDN is a very active poison and has been the cause of numerous poisoning accidents and health complaints following occupational exposure in the workplace. The toxicity of EGDN has been examined very thoroughly, and some observations and recommended workplace controls and cures may apply to other alkyl nitrates or alkylene dinitrates that are used in rocket propellants instead of the manufacture of dynamite. Like the effects of GTN in lowering blood pressure, the body eventually develops a greater tolerance to EGDN with prolonged exposure, but that does not mean that prolonged exposure is safe. An excess mortality from chronic cardio-cerebrovascular diseases among dynamite workers has been reported from the explosives industry. The exposure situation with regard to EGDN and GTN over the course of two decades in one of these factories was correlated to epidemiological statistical evaluation data of medical histories of workers [306]. The mean 8-h TWA concentrations of nitrate esters for

different job types were retroactively calculated from a large number of semiannually measured short-time samples. The concentrations in workroom air were estimated to have been in a range of 0.2–1.1 mg/m³.

EGDN can cause headaches, dizziness, nausea, vomiting, and abdominal pain and may affect the cardiovascular system, causing a decrease in blood pressure, resulting in lightheadedness. High levels can interfere with the blood's ability to carry oxygen (methemoglobinemia). Excessive exposure may result in death. Skin contact can cause a rash or burning feeling on contact. Exposure to small amounts of EGDN and/or NG by skin exposure, inhalation, or swallowing may cause severe throbbing headaches. The effects may be delayed.

EGDN may penetrate through rubber or cotton gloves similar to GTN. It appears that most of the occupational exposure to EGDN has occurred in dynamite production facilities where it was mixed with GTN. Although EGDN and GTN have a similar toxicity, the higher vapor pressure of EGDN caused most complaints to be due to inhalation and skin resorption of EGDN and not to GTN. Headaches have developed in workers exposed to 0.4 to 0.67 mg/m³ for 25 min, and all workers experienced decreases in blood pressure. Both EGDN and NG are vasodilators, and initial exposures result in headache, dizziness, nausea, or decreases in blood pressure. However, workers became tolerant of the vasodilatory activity after 2 to 4 d of exposure.

EGDN can be absorbed through skin contact as well as through inhalation and will cause hypotension, severe headaches, and methemoglobin formation. The rate of resorption through the skin was measured to be 0.4 mg cm⁻² h⁻¹ for humans and 6.5–10 mg cm⁻² h⁻¹ for rats [307]. The rate of resorption of EGDN through the skin was much faster than that of GTN.

9.1.3.1 Maximum Allowable Exposure Levels of Ethylene Glycol Dinitrate

PELs in air: Conversion factor: 1 ppm = 6.22 mg/m³ at 25°C and 1 atm.

The NIOSH REL for EGDN is 0.1 mg/m³ with a skin notation, and the same limit applies as an STEL. The OSHA PEL was 0.2 ppm (1 mg/m³) with a ceiling and a skin notation and was lowered on closer examination in 1989 to 0.1 mg/m³ as a STEL with a skin notation. The 1993-1914 ACGIH TLV was 0.05 ppm (0.31 mg/m³) TWA with a skin notation and was lowered to 0.02 ppm with a skin notation. The original NIOSH (SCP) IDLH was 500 mg/m³, which was lowered on closer examination to 200 mg/m³ and eventually lowered to 75 mg/m³ [308, 309]. The chosen IDLH for EGDN was based on chronic toxicity data concerning the physiological response of animals to EGDN. Rats and guinea pigs survived 6 months of exposure to 500 mg/m³ (80 ppm) EGDN, with the only effect being slight drowsiness and some Heinz body formation. It was stated that EGDN is more toxic for cats and rabbits, and the chosen IDLH is still probably conservative because cats given 2-h daily exposures to 21 ppm (133 mg/m³) EGDN for 1000 d exhibited only marked blood changes. There have been suggestions that these limits should be lowered for worker comfort [310].

The European Maximale Arbeitsplatz-Konzentration (MAK) limit is 0.05 ppm = 0.3 mg/m³. Already concentrations of 0.5 mg/m³ can cause headaches in workers exposed to EGDN vapors.

The intraperitoneal (IP) LD₅₀ in mice was 800 mg/kg and the IP LD₅₀ in rats was 616 mg/kg. The subcutaneous (SC) LD₅₀ in rabbits was 400 mg/kg and the SC LD₅₀ in cats was 100 mg/kg.

There have been extensive surveys of EGDN accumulation in the blood of workers exposed to EGDN vapors in the workplace [311, 312]. Blood samples were taken before, during, and at various intervals after the work shift. Health authorities have specified a maximum allowable EGDN concentration in the blood of workers at the end of the work shift of 0.3 µg EGDN/L blood. This number can be used to establish a biological exposure index (BEI) for monitoring worker health.

9.1.3.2 Toxicokinetics and Metabolism of Ethylene Glycol Dinitrate

EGDN concentrations in the blood and urine of dynamite production workers were measured [313]. Measurement of EGDN concentrations in the blood of 16 workers revealed undetectable levels prior to work in all of them. The amounts of EGDN detected after work were 0–145 ng/mL, high levels being noted in workers who had frequent exposure to skin absorption. Measurement of changes in blood EGDN concentrations and the EGDN excretion in urine in workers during a week revealed no persistent trend in blood EGDN concentrations, but a tendency toward higher EGDN concentration in urine was found in the afternoon. Urine samples are easier to obtain than blood samples and can be correlated to blood levels of EGDN.

Twenty percent of EGDN vapors in inhaled air are absorbed in the lungs, and exhaled air contains little EGDN [314]. At concentrations of 133–428 mg/m³ EDN in air, about 20% of the inhaled EGDN was resorbed in lung tissue with each breath.

The breakdown of EGDN in blood *in vitro* resulted in the liberation of inorganic nitrite and EGMN [315]. The nitrite was oxidized to inorganic nitrate, but the EGMN was more resistant to further degradation. Similar metabolites were produced during the metabolism of EDGN *in vivo*. The nitrate was excreted in the urine and accounted for 60% of the injection. The EGMN released was almost completely metabolized, since only 1.5% of the injection could be detected as EGMN in the urine. Breakdown of EGMN *in vivo* was confirmed when the compound was injected. Less than 0.5% was recovered as EGMN in the urine. Nitrite was released and oxidized to nitrate, which was then excreted in the urine and accounted for 57% of the injection. An injection of EGDN or EGMN caused a fall in blood pressure lasting several hours, EGDN being more effective. Since the fall in blood pressure and the concentrations of EGDN and its metabolites in the blood were determined simultaneously, a correlation between blood pressure and blood concentrations has been attempted. It was suggested that the fall in blood pressure after an injection of EGDN could be the result of the actions of EGDN, EGMN, and nitrite. The initial fall in blood pressure may be due to the intact molecule

of EGDN followed in turn by the effects of nitrite and EGMN released during the breakdown of the EGDN molecule.

During the *in vivo* metabolism of EGDN following repeated administration in the rat, and the *in vitro* metabolism of EGDN and NG following repeated administration in the rat and the dog, no changes were detected in the *in vivo* or *in vitro* metabolism after repeated injection, and the pattern of excretion of EGDN metabolites in the urine did not change [316]. It was suggested that the tolerance that developed to the cardiovascular effects of these compounds might be due to the changing influence of some physiological compensatory mechanisms rather than to any change in the pattern of metabolism.

The SC injection of 65 mg/kg EGDN, once daily, 5 d/week, for 5 weeks in the rat did not lead to any changes in the resting electrocardiogram (ECG), heart rate, or blood pressure once the immediate effects of the presence of unmetabolized EGDN in the blood had passed [317]. Five hours after the last injection of EGDN, the heart of the anesthetized rat was subsensitive to epinephrine-induced arrhythmias, and 24 h after the last injection both the heart and blood pressure were supersensitive to epinephrine. The absence of supersensitivity in the pithed rat indicated that the pressor supersensitivity of the intact, anesthetized rat was not due to the muscle cells of the cardiovascular system *per se* but must have involved the nervous system in some way. It was suggested that there might be some temporary deficiency in the circulatory mechanisms, in the baroreceptors, the higher autonomic centers, or the peripheral ganglia. It was suggested that the pressor supersensitivity might lead to myocardial sensitization in response to the extra-large fluctuation in blood pressure.

The effects of sustained exposure to EGDN at a rate of 50 mg/kg, 10 d on heart rate and mean arterial blood pressure, isolated strips from aorta and vena cava, catecholamine and DOPAC levels in brain, heart, adrenals and plasma, and synaptosomal uptake of noradrenaline have been investigated in rats [318]. Aortic strips showed a lower responsiveness to EGDN than control strips 2, 24, and 96 h after cessation of EGDN. Acute cumulative doses of EGDN induced a decrease in mean arterial blood pressure at all time intervals but 2 h after cessation of chronic EGDN-treatment, while noradrenaline induced a dose-dependent increase in mean arterial blood pressure. Mean arterial blood pressure was lower 2 h after cessation of EGDN than in the control rats, while heart rate was higher. After 24 h, mean arterial blood pressure was slightly higher than in the controls, and the heart rate was still elevated. It was suggested that prolonged exposure to EGDN not only induces tolerance at the cellular level but also interferes with arterial smooth muscle sensitivity to noradrenaline and with resetting of mean arterial blood pressure and heart rate.

The toxic effect of subcutaneously injected EGDN on the heart functions of rabbits was investigated by ECG [319]. The changes in the ECG patterns disappeared at 24 h after injection. The effect of EGDN on the heart tissues or the heart functions still remained days after, while no traces of EGDN were noticed in the blood.

In the EGDN metabolism, EGDN is first converted to EGMN, which converts to ethylene glycol more slowly and remains in the blood longer. There are enzymes that catalyze the hydrolysis of nitrate esters [320, 321].

An excellent summary of the toxicity of EGDN and a thorough compilation of data on which to base the establishment of safe exposure limits in the air of workplaces was published in German and is available for download on the Internet [322].

9.1.4 Handling Safety of Ethylene Glycol Dinitrate

EGDN has a DOT Hazard Classification of 1.1 when desensitized. EGDN must be shipped desensitized with 40% acetone and stabilized with 0.25% 2-NDPA. It can then be shipped under a DOT exemption permit as a Class A, Type 8 High Explosive. Stabilizers can be added on request.

Special gloves that prevent EGDN permeation through gloves must be worn when handling dynamite [323]. Permeation tests were performed on several protective clothing materials with NG- and EGDN-based explosive. Breakthrough times showed that the most resistant material was a nitrile rubber. Washing the gloves between uses was ineffective.

9.1.5 Safety Properties of Ethylene Glycol Dinitrate

The drop weight impact sensitivity of EGDN as measured in the BAM apparatus was 0.2 Nm. In another test with the BAM apparatus, for a steel weight of 1 kg, the tests with pure EGDN were positive for all heights, so sensitive that a “non-standardized” drop weight had to be used [298]. Subsequently, a mass of 0.534 kg, dropped at a height of less than 5 cm, gave six successive negatives. The 50% point with the smaller mass was at 0.133 J.

The friction sensitivity of EGDN as measured in the BAM apparatus was beyond the range of the apparatus, since at the maximum load of 353 N on the pistil no reaction was observed.

Card gap sensitivity tests were done with a 50:50 mix of EGDN:GTN and with Cavea-B in different diameter containers made from different container materials, starting with approximately 1-in. ID × 16-in.-long containers of varying wall thicknesses [324]. For 50–50 NG-EGDN the gap vs. wall thickness relationship for high-velocity detonation (approximately 7500 m/s) was found to have a negative slope in both steel and aluminum containers. This behavior is analogous to results obtained with Cavea-B-110 in steel, aluminum, and copper. For example, with card gaps of approximately 1.5 in. and 0.4 in., high-velocity detonations were observed for NG-EGDN in steel containers whose walls were 0.020 in. and 0.133 in. thick, respectively. Low-velocity reactions (approximately 2000 m/s or less) were obtained with NG-EGDN in 0.020-, 0.035-, and 0.133-in. wall thicknesses at gaps up to and including 12 in. For similar tests, see also [325, 326]. A shock sensitivity scale

for comparing double-base propellant casting solvents was established with the GTN/EGDN/triacetin system [327].

EGDN could be made to explode when tested for impact sensitivity in comparison to GTN and other energetic liquids [263].

In a U-tube adiabatic compression sensitivity test apparatus with variable, preselected push pressure and constant bubble size, the push pressure required to explode EGDN was higher than that of methyl nitrate or GTN, but similar to that of DEGDN [111].

9.1.6 Detonation Properties of Ethylene Glycol Dinitrate

In a lead block test, detonation of EGDN will enlarge the cavity by an impressive $620\text{ cm}^3/10\text{ g}$, one of the highest explosive yields measured by this method. The detonation velocity of EGDN confined in a steel tube is $7300\text{ m/s} = 24000\text{ ft/s}$ at $\rho = 1.48\text{ g/cm}^3$. Detonations in EGDN can propagate by LVD [328].

Theoretical predictions of detonation velocity and detonation pressure of EGDN from the Kamlet-Jacobs equation are 8960 m/s and 35.03 GPa , respectively [297].

9.1.7 Applications of Ethylene Glycol Dinitrate

EGDN was used mostly to lower the freezing point of GTN in the manufacture of dynamite. While initially in the early 1900s only 20% EGDN was in nitrate ester mixtures, the commonly used percentage had increased to 80% EGDN in the 1970s.

It is unfortunate that EGDN is one of the more easily produced liquid explosives for illicit uses. This required a stepped-up effort by the security authorities to detect vapors of EGDN in contraband smuggled by terrorists. The thermal stability and explosive performance of EGDN made in a clandestine laboratory from automobile coolant instead of laboratory-grade ethylene glycol was not much different from the pure substance [298]. The characteristics of the synthetic process (ease, yield), the chemical properties of the synthesized product (purity, spectra), and explosive properties (sensitivities, detonability) of EGDN prepared by various methods were investigated. Comparisons were drawn between clandestine products and the product obtained using pure laboratory ingredients. The explosives were analyzed by GCMS, IR, and DSC. The explosive properties of the pure synthesized products and improvised explosives were tested for their potential use as a priming/booster charge or as a main charge. The anti-corrosion additives in the automotive coolant did not interfere with the synthesis process.

9.2 1,1,2,2-Tetranitrateoethane

Geminal dinitrate esters form during the nitration of the geminal diol hydrated form of aldehydes. They can also be obtained via the addition of N_2O_5 to the double bond of

aldehydes. The other geminal dinitratoalkane is dinitratomethane, a liquid obtained by the nitration of 1,3,5-trioxane in a HNO₃/H₂SO₄ mixture [329].

Tetranitratoethane, tetranitroxyethane, C₂H₂N₄O₁₂, which has an oxygen content of 70.1 mass-% O, was synthesized by nitration of monomeric glyoxal using N₂O₅ and purified by sublimation [330]. Single crystals could be grown from CH₂Cl₂/pentane and were used to determine the structure by XRD. The X-ray structure revealed the material crystallizing in the orthorhombic space group *P*2₁/*c* with a density of 1.991 g/cm³ at 173 K. A DSC test with a heating rate of 5 °C/min indicated the material starting to decompose at 363 K (90 °C). Table 40 gives a comparison of properties of tetranitratoethane and those of other candidate oxidizers.

Table 40: Comparison of tetranitratoethane with other oxidizers.

Compound name	Tetranitratoethane	Ammonium perchlorate	Glycerol trinitrate	Pentaerythritol tetranitrate

Data source: [330]

Tetranitratoethane has a higher oxygen content than prominent solid oxidizers such as ammonium dinitramide (ADN), KClO₄, NH₄ClO₄, tetranitroacetimidic acid, and even tetranitromethane (TNM). The purified material is stable at room temperature under a dry atmosphere. In air it slowly hydrolyzes, forming nitric acid and glyoxal again. The hydrolysis, however, is slow enough to prevent the material from being hydrolyzed in ice water after quenching the reaction. Summarizing all the physicochemical properties of tetranitratoethane, especially the low thermal stability but also the high sensitivities would probably exclude any practical application of tetranitratoethane. Nevertheless, tetranitratoethane is a solid oxidizer carrying one of the highest oxygen contents ever synthesized.

9.3 C₃ Alkylpolynitrates

9.3.1 Propylene Glycol Dinitrates

There are two isomers of propylene glycol, the unsymmetrical 1,2-propylene glycol (the more common one since it is made by hydrolysis of propylene oxide, readily available from propylene) and the symmetrical molecule with the terminal hydroxyl groups in the 1 and 3 positions. Likewise, there are two dinitrate esters. If no other information is given, it is safe to assume that the information contained in publications without more specific nomenclature relates to 1,2-propylene glycol dinitrate (1,2-PGDN).

9.3.1.1 1,2-Propylene Glycol Dinitrate

1,2-Propylene glycol dinitrate, also known as 1,2-dinitratopropane, 1,2-propanediol dinitrate, methylglycol dinitrate, propylene dinitrate, dinitroxypropane, 1,2-PGDN, PGDN, $\text{CH}_3\text{CH}(\text{ONO}_2)\text{CH}_2(\text{ONO}_2)$, $\text{C}_3\text{H}_6\text{N}_2\text{O}_6$, molecular mass 166.09 g/mol, CAS RN [6423-43-4], is an important ingredient of a torpedo propellant called Otto Fuel II. Because it would be too sensitive and hot-burning if it was used in the undiluted state, it has been desensitized by addition of a non-energetic fuel with low volatility, di-*n*-butyl sebacate. It has been repeatedly tested as a gas generant for other applications and as a liquid gun propellant. The symmetrical isomer 1,3-PGDN is also called trimethyleneglycol dinitrate (Section 9.3.1.2):

9.3.1.1.1 Preparation of 1,2-Propylene Glycol Dinitrate

1,2-PGDN can be prepared from 1,2-propylene glycol with mixed acid. It can also be prepared by reaction of propylene with dinitrogen pentoxide. This reaction may actually take place uncontrolled to a minute extent in a polluted atmosphere. Products of the gas phase reaction of N_2O_5 with propylene in air were analyzed using a long-path FTIR spectrometer and a GC-EI and CI mass spectrometer [331]. This reaction may occur in the smog of highly polluted air.

To solve the problem of chemical waste during production of 1,2-PGDN with propylene oxide as raw material and a mixture of nitric acid and sulfuric acid as nitrating agent, a new method for preparation of PGDN by nitrating propylene oxide with dinitrogen pentoxide as a clean nitrating agent was developed [332]. This reaction is environmentally more friendly and economical. Effects of the sequence of addition, molar ratio of N_2O_5 to propylene oxide, reaction temperature and solvents on the yield and selectivity of PGDN were studied. The results showed that the optimum reaction conditions are: dropping the propylene oxide into the solution of N_2O_5 in an organic solvent, a molar ratio of N_2O_5 to propylene oxide above 1.1 : 1, the reaction temperature

288 K (15 °C) using dichloromethane as a solvent. Under these optimum conditions the yield of PGDN was about 96%, and the selectivity was nearly 100%.

Hygroscopic but thermally sensitive liquids such as PGDN (1,2-propanediol dinitrate)/DBS (dibutyl sebacate) mixtures can be sprayed at reduced pressure into a stream of dry, warm air to reduce the undesirable water content [333]. The effects of pressure, spraying times, propellant temperature and ventilation condition on spraying method dewatering efficiency were investigated. The results show that the water content in the propellant can be reduced from 0.2428 to 0.0614% under the conditions of 100 g batch size, pressure of 0.08 MPa, propellant temperature of 344 K (71 °C) and ventilation. The recovery was 100% and the treatment did not alter the thermal stability of the propellant.

9.3.1.1.2 Physical Properties of 1,2-Propylene Glycol Dinitrate

The physical properties of 1,2-PGDN are summarized in Table 41. See also [334, 335].

Table 41: Physical properties of 1,2-PGDN.

Property	SI units		Other units		References
Molecular mass	166.0895 g/mol		6.0208 mol/kg		[73]
Freezing point	230.9 K		−42.2 °C	−44 °F

Heat of evaporation at 288–328 K	63.8 kJ/mol	384.1 kJ/kg	15.2 kcal/mol	91.8 cal/g	[338]
Dielectric constant at 293 K (20 °C)	26.80				
Dipole moment	4.24 D				[10]

Vapor pressure data for PGDN in comparison to the vapor pressures of other glycol polynitrates were already shown in Table 6 above and Table 58 below.

The solubility of PGDN in water is 1.3 g/L. An IR spectrum of PGDN is shown in Figure 23.

Figure 23: Infrared spectrum of 1,2-PGDN. (Reproduced and modified from [296].)

The IR spectrum of PGDN in the gas phase differs appreciably from that of the neat liquid [331]. Comparison of the spectra indicated that three prominent peaks at about 1672, 1280, and 838 cm^{-1} in the PGDN spectrum can be assigned to the anti-symmetric NO_2 stretch, symmetric NO_2 stretch, and N—O stretch of PGDN (Figure 24).

Figure 24: IR spectrum of PGDN vapor. (Reproduced and modified from [331], with permission of Chemical Society of Japan.)

The IR spectrum of PGDN and six other dinitrate esters were computed by a DFT method [297].

A Raman spectrum of PGDN was shown in Figure 2 above in comparison to the Raman spectrum of GTN [25, 26].

9.3.1.1.3 Physical Properties of 1,2-Propylene Glycol Dinitrate Mixtures

The most prominent mixture of 1,2-PGDN is Otto Fuel II, a torpedo propellant used mostly in the US Navy's MK-46 and MK-48 torpedoes, but also in torpedoes of other navies worldwide. Otto Fuel II consists nominally of 76% 1,2-PGDN as the energy source, 22.5% dibutyl sebacate as a desensitizer, and 1.5% 2-NDPA as a stabilizer.

Because so many publications deal with the chemistry of Otto Fuel II, it has even been assigned its own Chemical Abstracts System Registry Number, CAS RN [106602-80-60]. The properties of Otto Fuel II are summarized subsequently in Section 9.3.1.1. 1,2-PGDN forms an azeotrope with water, which enhances its volatility.

9.3.1.1.4 Chemical Properties of 1,2-Propylene Glycol Dinitrate

The oxygen balance of 1,2-PGDN is -28.9%, and the nitrogen content is 16.87 mass-% N.

Analysis of 1,2-Propylene Glycol Dinitrate

The purity requirements for PGDN that is to be used for torpedo propellants such as Otto Fuel II are spelled out in [339]. Analytical methods per DOD-P-82671 used to verify the purity of PGDN include the following methods: total nitrogen content per MIL-STD 286B, Method 209 (16.82–16.92 mass-%N), free acidity (or alkalinity) (0.001 mass-% max.), moisture content by Karl Fischer reagent (0.5 mass-% H₂O max.), and thermal storage stability as indicated by a potassium iodide-starch paper test strip suspended in the gas space above the sample heated to 355.3 K (82.2°C) (no reaction within 10 min).

1,2-PGDN, the main ingredient in Otto Fuel II, can be detected and quantified in aqueous solution down to the ppm level by HPLC separation and UV detection [340]. The method developed was applied to evaluate the efficiency of organic solvent extractions of PGDN from wastewater solutions generated at CFAD Bedford during maintenance of the MK37 and MK44 torpedoes. The results indicated that less than 1 ppm PGDN remained in solution following extraction.

A rapid and specific polarographic method for analyzing PGDN in wastewater uses a portable and inexpensive digital polarograph and monitoring system for the field analysis of PGDN in effluent water from a Navy carbon column cleanup process to remove the PGDN from Otto Fuel wastewater [341–343]. Data obtained by this method of analysis and field equipment compared favorably with data obtained by a more time-consuming vapor-phase GC method on the same samples of effluent water.

PGDN in the air of workplaces can be detected by a sensitive piezoelectric quartz crystal microbalance with a coating that has high affinity toward PGDN [344]. The in-

strument is sensitive to below 0.05 ppm and selective for PGDN and suffers no interference from humidity.

Mono- and dinitrated propylene glycols can be separated and detected using either a gas chromatographer equipped with a nitro-specific thermal energy analyzer (GC/TEA) or a HPLC equipped with an electrochemical detector in reductive mode (LC/EC) [345]. The GC/TEA exhibited a linear range of response of three orders of magnitude and provided detection limits in the $\mu\text{g/mL}$ range for these three compounds. The LC/EC had a linear response over two orders of magnitude and was best suited for the determination of PGDN.

1,2-Propanediol dinitrate poisoning in blood at concentrations ranging from 10 ng/mL up to 25000 ng/mL can be analyzed by GC with electron-capture detection using double ether extraction with manual shaking in order to complete sample preparation within 5 min [346].

Photolysis of 1,2-Propylene Glycol Dinitrate

Surprisingly, mono- and difunctional alkyl nitrates are common products of atmospheric reactions of NO_3 radicals with unsaturated hydrocarbons. The UV absorption spectra of several organic dinitrates and keto nitrates have been measured in the gas phase at 298 K and atmospheric pressure: 1,2-propanediol dinitrate, $\text{CH}_3\text{CH}(\text{ONO}_2)\text{CH}_2(\text{ONO}_2)$; 1,2-butanediol dinitrate, $\text{CH}_3\text{CH}_2\text{CH}(\text{ONO}_2)\text{CH}_2(\text{ONO}_2)$; 2,3-butanediol dinitrate, $\text{CH}_3\text{CH}(\text{ONO}_2)\text{CH}(\text{ONO}_2)\text{CH}_3$; and five others [347]. Although the UV spectra of the nitrates were all very similar in shape, the cross sections of the dinitrates were a factor of 2 higher than those reported in the literature for the corresponding alkyl mononitrates. The UV absorption cross sections of the difunctional nitrates were used in combination with solar actinic flux data to estimate photolysis frequencies and, consequently, atmospheric lifetimes for these compounds. The results indicated that for the saturated difunctional nitrates, photolysis will generally be somewhat more important than reaction with $\cdot\text{OH}$ radicals as an atmospheric removal process.

9.3.1.1.5 Safety Properties of 1,2-Propylene Glycol Dinitrate

Although PGDN is used mostly for underwater propulsion and not above ground or even in space, the safety properties of PGDN are summarized here in detail because they may relate to the safety properties of other nitrate esters that are actively being used as rocket propellant ingredients. Methods of analysis and safety evaluation for all these alkyl nitrates would be very similar.

Most safety tests for 1,2-PGDN were done in connection with its use in Otto Fuel II. The current section and a similar section specifically for Otto Fuel II further down overlap to some extent.

Toxicity of 1,2-Propylene Glycol Dinitrate

Most toxicity tests for 1,2-PGDN have been done in connection with its use in Otto Fuel II. As a matter of fact, in a few instances Otto Fuel II was used as a source of PGDN vapor because the other ingredients have only negligible vapor pressure. The current section and a similar one specifically for Otto Fuel II overlap to some extent. 1,2-PGDN is a systemic toxicant with effects on the cardiovascular and central nervous systems. Its vasodilatory action results in headaches during human exposure. Dizziness, loss of balance, nasal congestion, eye irritation, palpitations, and chest pains have been reported. The air-odor threshold in healthy human subjects is 0.2 ppm, but warning properties are poor inasmuch as olfactory fatigue sets in after as little as 5 min [348]. PGDN is rapidly and completely metabolized *in vivo* and eliminated primarily in the urine as inorganic nitrate within 24 h of exposure. Inhalation or resorption of PGDN through the skin causes headaches and cumulative disruption of the visual evoked response, marked impairment of balance and coordination, and eye irritation at exposure levels of 0.2 ppm or greater. The *per os* (PO) LD₅₀ in rats is 250 mg/kg.

An excellent review of toxicity evaluation of PGDN and Otto Fuel II is given in [349].

The ACGIH recommended TLV/TWA was 0.02 ppm = 0.2 mg/m³ in air but the more recent NIOSH REL TWA is 0.05 ppm (0.3 mg/m³) with a **skin** notation.

Two excellent summaries on the toxicity of PGDN were prepared by the National Research Council US Subcommittee and used as the basis to establish tolerable level of exposure of humans to PGDN in the workplace. One was used to establish Acute Exposure Guideline Levels (AEGs) for PGDN [350]. The two books were posted on a web site of the National Center for Biotechnology Information and provided as e-books as PDFs for download by the general public. Those publications, just one of the five or six chapters in each book, are the best summaries on the toxicity of any rocket propellant or energetic material referenced in our book. The style of the publication is accurate, comprehensive, and (as of 2002 and 2009) up to date. Several sections of those studies would fit right in here without any modification. Several sentences have been selected for inclusion in this book. A few years after the first book, an updated summary of toxicity of PGDN as it may affect submarine atmospheres was published by the National Research Council [351]. That book's Chap. 6 summarized epidemiologic and toxicological studies of PGDN. It presented selected chemical and physical properties, toxicokinetic and mechanistic data, and recommended inhalation-exposure threshold levels from the National Research Council and other agencies. The committee considered all that information in its evaluation of the US Navy's 1-h, 24-h, and 90-d exposure guidance levels for PGDN and issued recommendations for PGDN EEGL and CEGl exposure levels shown in Table 42.

Because PGDN is the primary and most toxic component of Otto Fuel II and because only PGDN is relatively volatile compared to the other components, AEGs have been derived in terms of PGDN with the notation that the values are appropriate for Otto Fuel II as well (Table 43). Additional information is in the meeting minutes of

Table 42: Emergency and continuous exposure guidance levels for PGDN.

Exposure level	US Navy Values ppm	Committee recommended values ppm
EEGL 1-h	0.15	0.2
EEGL 24-h	0.02	0.02
CEGL 90-day	0.01	0.004

CEGL = Continuous Exposure Guidance Level; EEGL = Emergency Exposure Guidance Level

Data source: [351]

Table 43: Summary of AEGL values for PGDN (Otto Fuel II).

Classification	Units	10 min	30 min	1 h	4 h	8 h	End point	References
AEGL-1 ^a , Non-disabling	ppm	0.33	0.33	0.17	0.05	0.03	Mild headaches in humans	[348]
	mg/m ³	2.3	2.3	1.1	0.34	0.17		
AEGL-2, Disabling	ppm	2.0	2.0	1.0	0.25	0.13	Severe headaches and slight unbalance in humans	[348]

	mg/m ³	114	114	93	57	38		

^a The distinctive odor of PGDN will be noticeable to most individuals at the 0.33- and 0.17-ppm concentrations.

Data source: [350]

the National Advisory Committee for Acute Exposure Guideline Levels for Hazardous Substances [352].

Experimental Animal Exposure Tests

In a study of the acute toxicological parameters of PGDN, EGDN, and GTN both *in vivo* and *in vitro*, the LD50 was determined in a strain of albino female mice by IP injection of a 2% solution of each compound in a 10% soy oil emulsion [354]. Twenty mice were dosed in each group. Five dose levels were set at logarithmic increments. LD50 determinations revealed PGDN at 930 mg/kg (800–1075, 95% confidence interval), EGDN at 800 mg/kg (661–964), and GTN at 194 mg/kg (164–228). GTN was about four times as toxic to mice as the other two nitrated esters. Mice exposed to GTN expired within 1 h of injection and suffered convulsions. Expiring animals in the groups exposed to PGDN and EGDN did not exhibit premorbid convulsions and most exceeded 1 h to demise. For a study of the blood elimination in 2.5-kg rabbits, each compound was injected

as a single dose of 1 mg/kg body weight in one femoral vein, while serial arterial and venous samples were taken on the contralateral side. Samples were assayed for each compound by GC. At 1 min, 15% of injected PGDN was found in arterial blood and 3 to 5% in venous samples. By 2 min, the rates of elimination for PGDN, EGDN, and GTN were the same. This indicated an extremely rapid breakdown, exhibiting first-order kinetics with only slight differences among PGDN, EGDN, and GTN.

The LD₅₀ values of PGDN were determined in the rat, mouse, and cat [355]. Injection of LD₅₀ in rat caused almost complete conversion of the hemoglobin to methemoglobin, indicating that methemoglobinemia was the principal cause of death following PGDN administration. The metabolism of PGDN *in vitro* and *in vivo* gave rise to inorganic nitrite and inorganic nitrate, and the 1- and 2-isomers of propylene glycol mononitrate. The 2-isomer predominated, and it was suggested that there was a reaction favoring its formation. *In vivo* the mononitrates were themselves metabolized with the result that only small amounts are excreted. The major urinary metabolite was inorganic nitrate, accounting for 56% of the original injection of PGDN. PGDN is a potent vasodilator in animals, inducing a maximal fall in blood pressure usually 30 min after injection. An injection in the rat gave rise to a fall in blood pressure lasting several hours that might have been due to the combined influence of the intact molecule of PGDN and its metabolites. It was concluded that there was little to distinguish the metabolism and pharmacology of PGDN from those of EGDN. Rats treated with lethal oral or subcutaneous doses of PGDN were prostrate, anoxic, and cold and had signs of methemoglobinemia and respiratory depression. At high oral or parenteral doses, deaths from anoxia due to almost complete conversion of hemoglobin to methemoglobin have been observed. Death consistent with anoxia occurred up to 48 h after PGDN administration. Oral doses of PGDN that were lethal to half the animals ranged from 250 to 1190 mg/kg in rats.

Comparing the toxicity of TEGDN and PGDN it was observed that in most species the LD₅₀ of TEGDN was two to five times as high as that of PGDN [356]. Both compounds produced methemoglobinemia and hypotension in rats. PGDN-poisoned rats were lethargic and did not convulse. Chronic daily dermal applications to rabbits of 21 mmol/kg of either dinitrate caused death in 2 to 3 weeks. PGDN-treated rabbits gained weight normally, while those treated with TEGDN lost 20 to 30% of their body weight. The toxic responses of these two dinitrates were sufficiently different to preclude simple comparisons in hazard evaluations.

Bolus injections of PGDN were made intravenously to dogs at four (4, 10, 40, and 100 mg/kg) dose levels [357]. Dynamic effects were dose related and both physiological and biochemical in nature. The physiological changes were maximized during the fast distribution phase of PGDN in the central compartment. These included the vasodilation effects of decreased systolic, diastolic, and pulse blood pressures. A reflex increase in heart rate ensued, which was significantly dose related with a maximum attainable increase of 129.5 beats/min. One biochemical manifestation of PGDN intoxication was an increase in methemoglobin. Urine production, presumably changed

due to blood pressure, decreased inversely with PGDN dose. An unexpected occurrence associated with this decrease was the appearance of whole blood cells in the urine.

Inhalation Toxicity and Behavioral Changes

Inhalation exposure of eight male Sprague-Dawley-derived rats to PGDN at about 10 ppm 7 h/d, 5 d/week for a total of 30 exposures did not result in death or adverse clinical signs [353]. Weight gain, hematologic values, and histopathologic examinations of heart, lungs, liver, spleen, and kidneys did not reveal adverse effects immediately after exposure (four rats) or 2 weeks later (four additional rats). In the exposed 4 species of animals used for inhalation tests, 9 male squirrel monkeys, 2 male beagles, 15 male and 15 female Sprague-Dawley-derived rats, and 15 male and 15 female Hartley-derived guinea pigs per exposure concentration to PGDN at 10, 16, or 35 ppm continuously (24 h/d) for 90 d, physiological and biochemical changes noted were anemia, pigment deposition in various organs, fatty changes in the liver, methemoglobin formation, and greatly increased serum and urinary inorganic nitrates. Three trained male squirrel monkeys were exposed to PGDN continuously for 90 d at 39 ppm. The animals were removed from the exposure chambers for a 2-h period once a week and tested. There were no changes in avoidance behavior in the monkeys.

Free operant avoidance behavior and visual evoked responses of rhesus monkeys exposed to 2–33 ppm PGDN vapors on either an acute or chronic schedule were monitored for several weeks [358]. Free operant avoidance was not affected at any dose level.

Rats were evaluated as a model animal to measure PGDN-induced motor performance decrement and to determine whether direct application of PGDN to neural tissue would be a useful alternative to other routes of exposure [359]. PGDN was injected onto the cisterna magna of adult rats trained on the accelerod, a test of motor performance. Three groups of 13 or 14 male rats each received a single dose of either 5 or 10 μ L PGDN or 25 μ L sterile saline (control) while anesthetized with halothane. Accelerod performance was measured 12 min after IC injection, then hourly for 6 h and at 24 h. A significant decrease in performance occurred during the first 2 h following injection of 10 μ L PGDN compared to the control and the 5- μ L groups. No significant differences were seen between the 5- μ L and control groups. The data indicated that IC injection may be an effective alternative to other routes of dosing exposure.

Nitrate ester explosives block monoamine oxidase (MAO) MAO metabolism and nerve conduction. The effect of the organic nitrate explosives GTN, PGDN, EGDN, and their metabolites on mitochondrial MAO activity of rabbit liver was studied *in vitro* with a method using tryptamine labeled with radioactive carbon as a substrate. The MAO activity was inhibited by the three explosives, while their metabolites had no such effect [360, 361]. See also [362, 363].

Blood Toxicity

Methemoglobinemia has been observed at the highest concentrations used in exposure studies with animals. Interspecies variability of PGDN-induced methemoglobin formation was studied *in vitro* employing erythrocytes from four separate species [364]. In a series of *in vitro* assays using blood, hemolysates, and partially purified hemoglobin solutions, the formation of methemoglobin was greatest in the dog and less in the guinea pig, followed by the rat; the human was either the least sensitive or as sensitive as the rat. The net rate of methemoglobin formation was significantly different among species with dog guinea pig rat human.

Oral Toxicity

The PO toxicity of PGDN in rats and the ocular and dermal irritation effects of PGDN on rabbits were determined in carefully conducted animal exposure tests [353]. Rats, guinea pigs, rabbits, squirrel monkeys, and dogs were exposed to the vapors of PGDN in acute, repeated, and continuous inhalation exposures.

Rats treated with lethal oral doses of PGDN were prostrate, anoxic, and cold and had signs of methemoglobinemia and respiratory depression. At high oral doses, deaths from anoxia due to almost complete conversion of hemoglobin to methemoglobin have been observed. Oral doses of PGDN that were lethal to half the animals ranged from 250 to 1190 mg/kg in rats.

Mutagenicity of Otto Fuel II

Otto Fuel II was examined for mutagenic activity in a series of *in vitro* microbial assays employing *Salmonella* and *Saccharomyces* indicator organisms [365]. The low dose in all cases was below a concentration that demonstrated any toxic effect. The dose range employed for the evaluation of this compound was from 0.005 to 10 μ L per plate. The compound was toxic to all the strains except TA-1538 and D4 at 5 and 10 μ L per plate. Toxicity was also observed with the strain TA-1535 at 1 μ L per plate. The results of the tests conducted on the compound in the absence of a metabolic system were all negative. The results of the tests conducted on the compound in the presence of the rat liver activation system were all negative. The test was repeated with TA-100 at the three lowest doses and intermediate doses of 0.05 and 0.5 μ L per plate, and the repeat tests were also negative.

Carcinogenicity of Otto Fuel II

In a 1-year industrial type (6h/d, 5d/week) of test animal inhalation exposure to evaluate the oncogenic potential of Otto Fuel II, the exposure levels were 1.4 and 240 mg/m³ [336]. Dogs (male and female beagle), rats (male and female Fischer 344), and mice (male and female C57BL/6) were exposed to the lower concentration, while only rats and mice were exposed to the higher concentration. Dogs appeared to be the most sensitive species tested with measurable reductions in RBC, hematocrit, and hemoglobin levels. Mildly increased methemoglobin was also observed in dogs

exposed to 1.4 mg/m^3 and rats exposed to 240 mg/m^3 . No other significant effects were noted in rats exposed at either concentration. Microscopic examination of tissues collected from dogs, rats, and mice exposed to Otto Fuel II vapors failed to suggest any significant exposure-related non-neoplastic changes. Similarly, exposure to Otto Fuel II also failed to increase the incidence of neoplastic changes.

Teratogenicity of Otto Fuel II

Four groups of time-mated rats were treated dermally at rates of 0, 400, 2000, and $4000 \text{ mg kg}^{-1} \text{ d}^{-1}$ with Otto Fuel II to study developmental toxicity in the fetuses [366]. A significant reduction in maternal body weight was seen at necropsy in dams receiving 2000 and $4000 \text{ mg kg}^{-1} \text{ d}^{-1}$ of Otto Fuel II. Fetuses from these dams also weighed significantly less than control fetuses. Phase II of the investigation involved dosing of artificially inseminated rabbits with Otto Fuel II. The fuel was administered to the skin of the animals' back at the rate of 0, 100, 316, and $1000 \text{ mg kg}^{-1} \text{ d}^{-1}$. Maternal toxicity was evidenced by a significant reduction in the body weight of the dams in the $1000 \text{ mg kg}^{-1} \text{ d}^{-1}$ dose group on days 20 and 25 of gestation. There were no significant differences observed in maternal weight or fetal weight at necropsy. Morphological examination of both rat and rabbit fetuses failed to reveal significant evidence of fetal malformations.

Human Volunteer Exposure Tests

At low concentrations, PGDN has been reported to cause cardiovascular, irritant, and central nervous system effects including headaches, nasal congestion, eye irritation, and dizziness in humans.

Primarily young male volunteers were exposed to PGDN vapors under carefully controlled conditions at various concentrations (0.03, 0.1, 0.2, 0.35, 0.5, and 1.5 ppm) for 1 h or longer [348, 367]. Three of six volunteers or research staff members who were exposed to PGDN at 0.5 ppm for 1–1.25 h developed mild headache but had no other adverse effects. At 1.5 ppm, eight subjects reported mild eye irritation within 40 min of exposure, which resolved on cessation of exposure. Marked impairment in balance became noticeable after exposure to 0.5 ppm for 6.5 h, while 40 min of exposure to 1.5 ppm added eye irritation to the list of symptoms. All the volunteers developed severe frontal headaches after only 30–90 min of exposure, so all exposures were terminated after 3 h, at which time the headaches were described as nearly incapacitating. The headaches persisted for 1–7.5 h in the absence of continued exposure. Coordination tests were abnormal while the subjects were experiencing severe headaches. The visual evoked response in all volunteers showed a dramatic increase (of 10–70%) in amplitude in the peak-to-peak voltage of the 3-4-5 complex after 45–90 min of exposure. The amplitude shifted toward normal after cessation of exposure but was still altered 48 h after exposure. Those data indicated a threshold after a 1-h exposure to PGDN at 0.5–1.5 ppm for the induction of severe headaches that can be incapacitating and impair function.

The air-odor threshold in healthy subjects was 0.2ppm, but warning properties were poor inasmuch as olfactory fatigue was reported to set in after as little as 5 min [348].

Occupational Exposure Monitoring

The neurophysiologic effects of acute and chronic exposure to PGDN of 87 workers employed in US Navy torpedo facilities were evaluated by interviews and review of medical records [368]. Prior to the evaluation, the subjects reported subjective symptoms of frequent or occasional headaches (65% of respondents), nasal congestion (31%), eye irritation (26%), and dizziness (13%). Palpitations, dyspnea, chest pain, and loss of balance were reported by small percentages of workers. For chronic exposure, evaluation of the workers included both quantitative oculomotor functions (eye tracking movements) and ataxia tests. Comparisons were made with a control group consisting of 21 non-exposed personnel from the same facilities. Results of the tests indicated no evidence of chronic neurotoxicity in either the study population or a subgroup of 28 workers with the longest exposure to PGDN. Acute effects were evaluated in a subgroup of 29 workers by comparing test values before and after a torpedo maintenance procedure. The maintenance procedures lasted 30–60 min. During this time, PGDN concentrations, as indicated by approximately 400 grab samples taken in the work area, ranged from 0.00 to 0.22 ppm (average value of 0.06 ppm; 88% were ≤ 0.1 ppm, 50% were ≤ 0.05 ppm, and only one sample was above the ACGIH TLV-Ceiling value of 0.2 ppm, which was in effect at that time).

Unintentional Human Exposure Epidemiological Studies

Epidemiological studies evaluated cardiac morbidity among the US Navy's torpedoman's mates, a group of servicemen potentially exposed to PGDN while engaged in torpedo maintenance work [369–371]. Cardiovascular events in this group were compared with both a non-exposed group of torpedomen and a non-exposed group in the job category of fire control technician. The torpedoman's mate group consisted of 1352 men, with an average yearly population of 822; hospitalization records were available for 10 years. The non-exposed-torpedomen control group consisted of 14336 individuals over the 10-year period with a yearly average of 4906. The fire control technician control group consisted of 29129 individuals with a yearly average of 11198. Measured concentrations of PGDN included those of the Horvath et al. [368] study and more recent surveys in which 8-h TWA were below 0.05 ppm. Cardiac incidents considered were myocardial infarction, angina pectoris, and cardiac arrhythmia. There were higher incidences of hospitalizations for myocardial infarctions and angina pectoris but not cardiac arrhythmias in the torpedoman's mates group than in either control group. Relative risk and stress in working with explosive devices were significant for myocardial infarction and angina pectoris when compared with the torpedoman's control group (2.6 and 3.8, respectively; $p < 0.05$) but not when compared with the fire control technicians. When incidences

of myocardial infarction and angina pectoris were combined, relative risk was significant when compared with both the unexposed torpedoman's and fire control technician control groups (2.6 and 2.9, respectively; p 0.05).

Environmental Effects of 1,2-Propylene Glycol Dinitrate

Soil Degradation of 1,2-Propylene Glycol Dinitrate

Previously, bacterial cultures were isolated that had the ability to degrade the nitrate ester GTN. An attempt was made to induce *Bacillus* sp. ATCC 51912 to degrade the more recalcitrant nitrate ester PGDN [372]. It was observed that the PGDN-denitrating activity was expressed during growth, even when sensitized cells were cultured in the absence of nitrate esters. Using cell-free extracts, PGDN was observed to be sequentially denitrated to propylene glycol mononitrate and propylene glycol with the second denitration step proceeding more slowly than the first.

Investigation of the biodegradability of PGDN, the major component of Otto Fuel II, has shown that this compound was resistant to biodegradation by microorganisms found in sewage sludge, a pure culture of *Pseudomonas aeruginosa* (previously shown to capable of biodegrading nitroaromatic explosives), and a commercially available inoculum, used for the degradation of nitrogen-containing organic wastes [373]. However, PGDN is photolabile in ultraviolet, decomposing to pyruvic and lactic acids. In biodegradation experiments, PGDN rapidly evaporated from aqueous solutions. This unexpected volatility of PGDN, which poses a potential health hazard, was attributed to the formation of a PGDN-water azeotrope, whose presence was demonstrated by partition experiments.

Explosive Sensitivity of 1,2-Propylene Glycol Dinitrate

PGDN will detonate if initiated with a No. 8 blasting cap. The impact sensitivity was 57.5 cm using a 5-kg mass. In the Allegheny Ballistics Laboratory (ABL) sliding friction test apparatus (metal to metal), the material did not ignite at the maximum setting of the apparatus 4.36 kN (980 lb_f). In the electrostatic sensitivity tester, all tests were negative at 8.75 J.

9.3.1.1.6 Explosive Performance of 1,2-Propylene Glycol Dinitrate

1,2-PGDN is shock sensitive and is a liquid explosive. In the lead block test, the enlargement of the cavity was 540 cm³/10 g, which was 92% of that of NG or 157% of that of TNT. The detonation velocity of confined PGDN was 6885 m/s at 1.38 g/cm³.

9.3.1.1.7 Propellant Mixtures with 1,2-Propylene Glycol Dinitrate

The main application of 1,2-PGDN is as a monopropellant in Otto Fuel II, a torpedo propellant. Although 1,2-PGDN by itself would be a powerful monopropellant, it is too sensitive to be used in the undiluted state. The diluent (solvent, desensitizer) used to desensitize PGDN is di-*n*-butyl sebacate. Although we would rather go up than go

down, the properties of Otto Fuel II are listed here because there may be other applications for it.

Composition of Otto Fuel II

The nominal composition of Otto Fuel II as specified by MIL-O-82672A [374] is listed in Table 44, along with a list of military specifications that cover the procurement of the ingredients to be mixed in making Otto Fuel II.

Table 44: Nominal composition of Otto Fuel II.

Ingredient	Requirement		as per MIL SPEC
	Minimum, mass-%	Maximum, mass-%	
1,2-PGDN	75.8	76.2	DOD-P-82671
2-Nitrodiphenylamine	1.4	1.6	MIL-N-3399B
Di- <i>n</i> -butyl sebacate	22.2	22.8	DOD-B-82669
Sodium		0.8 ppm	—
Moisture		0.1	—

Production of Otto Fuel II

The US Naval Surface Warfare Center's Indian Head Division (NSWC IHD) closed out a chapter in its long history with a commemorative ceremony that marked the final operation for a five-decade old nitration facility in 2011. Constructed in 1954, the Bi-azzi Nitration Facility allowed Indian Head to make NG in a continuous as opposed to batch process. In the early 1960s, the Bi-azzi plant was modified to produce Otto Fuel II for torpedoes and has been the sole producer of that fuel since 1971. Otto Fuel II is (was) used in many of the US Navy's torpedoes and was also used by 26 US allies. For several years, NSWC IHD ramped up production of Otto Fuel II to cover any potential shortfall while a new state-of-the art nitration facility was being built. The new facility, which will be remotely operated, modernized nitration procedures, is safer to operate and significantly reduced the facility's environmental footprint. As of 2011, NSWC IHD produced Otto Fuel II for all domestic and foreign allies' torpedoes [375].

Physical Properties of Otto Fuel II

A useful summary of physical properties of Otto Fuel II over a wide range of temperatures and pressures was given in [376]. Several of the graphs in this section of our book were copied from that source.

Dry Otto Fuel II freezes at 241 K (−32°C). The melting point depends on water impurity levels and may range from 241 to 237 K (−32 to −36°C).

Physical properties of Otto Fuel II are summarized in Table 45.

Table 45: Physical properties of Otto Fuel II.

Property	SI units	Other units
Freezing point	241 K	−32 °C
Density at 298 K	1.2314 g/cm ³	
Isothermal compressibility at 101 kPa	5.324 × 10 ^{−7} kPa ^{−1}	
Viscosity at 273 K	0.011 Ns/m ²	11.0 cPs
Viscosity at 293 K	0.005 Ns/m ²	5.0 cPs
Viscosity at 298 K	0.004 Ns/m ²	4.04 cPs
Surface tension	34.45 × 10 ^{−5} N/cm at 298 K	34.45 dyn/cm at 25 °C
Thermal conductivity at 278 K	1490 W m ^{−1} K ^{−1}	
Thermal conductivity at 333 K	1400 W m ^{−1} K ^{−1}	
Specific heat at 303 K	1.88 J g ^{−1} K ^{−1}	0.45 cal g ^{−1} °C ^{−1}
Dielectric constant at 296 K	18.8	
Electrical conductivity at 296 K	14.2 μ MHO/m	

Data source: [376, 336]

The density as a function of temperature in the range 258 to 338 K (−15 to +65 °C) can be calculated from the equation

$$\rho = 1.2595 - 0.001155t$$

Figure 25: Density of Otto Fuel II as a function of temperature with pressure as auxiliary parameter. (Reproduced and modified from [376].)

where ρ is the density in g/cm³ and t is the temperature in °C. The density of Otto Fuel II as a function of temperature with the pressure as auxiliary parameter is shown in Figure 25.

The thermal coefficient of expansion of Otto Fuel II is illustrated in Figure 26.

Figure 26: Thermal coefficient of expansion of Otto Fuel II. (Reproduced and modified from [376].)

The compressibility of Otto Fuel II is shown in Figure 27.

The vapor pressure of Otto Fuel II that is not perfectly dry is caused mostly by the low water content. The vapor pressure of freshly dried Otto Fuel II is very low, 9.7 Pa (0.0728 mm Hg) at 298 K (25 °C) and 456 Pa (3.424 mm Hg) at 348 K (75 °C). The vapor pressure of its most hazardous ingredient, pure PGDN, in the absence of the desensitizer at 298 K (25 °C) would be 13 Pa (0.09844 mm Hg). The dynamic viscosity of Otto Fuel II is illustrated in Figure 28.

The maximum dissolved water content in Otto Fuel II before phase separation occurs is 0.31 mass-% H₂O at 298 K.

Figure 27: Compressibility of Otto Fuel II. (Reproduced and modified from [376].)

Figure 28: Dynamic viscosity of Otto Fuel II. (Reproduced and modified from [376].)

Thermodynamic Properties of Otto Fuel II

Table 46: Heat of formation of Otto Fuel II assuming additive behavior.

Ingredient	Composition	Molecular mass g/mol	Enthalpy of formation		
	Mass-%		kJ/mol	J/g	J/%g
1,2-PGDN	76	166.09	-296.9 ± 9.3	-1788 ± 56	
2-Nitrodiphenylamine	1.5	214.22	+121.0	+565	+8.472
Di- <i>n</i> -butyl sebacate	22.5	314.47	-1156.7	—	—
Total	100				

The US Navy PEP computer program ingredient list PEPCODED.DAF lists three different sets of data for Otto Fuel II, but we don't know which one is the more accurate one [377]:

Name	Formula		cal/g	lb/cu. in.
726 OTTO II	471C 876H 5520 155N	00	-696	.0452
727 OTTO II	274C 526H 3060 ~94N	00	-696	.0452
728 OTTO II GARY	295C 565H 3280 100N	00	-526	.0448

It is not known which of the three sets is the most accurate to be used for performance calculations.

Chemical Properties of Otto Fuel II

The chemical properties of Otto Fuel II are determined mostly by its main ingredient, 1,2-PGDN. As such, it will react with bases and strong acids.

Decomposition Reactions of Otto Fuel II

In this section we only cover the slow decomposition of Otto Fuel II during storage and thermal stability tests. The strand burning of 1,2-PGDN and its mixtures such as Otto Fuel II will be discussed in *Encyclopedia of Monopropellants*.

Thermal Stability of Otto Fuel II

Otto Fuel II is thermally stable at temperatures up to 339 K (150 °F) for several years, up to 355 K (180 °F) for a few months and up to 394 K (250 °F) for perhaps 30 min. Above 394 K (250 °F) there is a danger of instant exothermic decomposition in a runaway reaction. The AIT of Otto Fuel II is 394 K (121 °C).

Storage Stability of Otto Fuel II

A sample of Otto Fuel II has been held at a temperature of 323 K (122 °F) for over 7 years with no sign of deleterious effects. In another test, Otto Fuel II in a Mark 46 Mod 1 torpedo tank was stored at 336 K (145 °F) for 6 months with only minor changes [378].

The long-term storage properties of Otto Fuel II were investigated by elevated-temperature aging tests, natural environment storage tests and hydrothermal environment metal compatibility (causticity) tests [379]. Results showed that its safe storage life estimated at 303 K (30 °C) is not less than 11 years and its ingredients unchanged after stored for 2.4 years under ambient environment conditions. The water content in Otto Fuel II was nearing saturation after stored at 333 K (60 °C), 85% relative humidity for 30 d, but the content of the stabilizer and nitric acid ester was constant.

Analysis of Otto Fuel II

The nominal composition of Otto Fuel II as specified by MIL-O-82672A [374] is listed in Table 47.

Table 47: Specification requirements for Otto Fuel II.

Requirement	Minimum, mass-%	Maximum, mass-%
PGDN	75.8	76.2
2-Nitrodiphenylamine	1.4	1.6
Di- <i>n</i> -butyl sebacate	22.2	22.8
Sodium		0.8 ppm
Moisture		0.1

The methods for the chemical analysis of Otto Fuel II for quality control are described in Military Specification MIL-O-82672A. The PGDN content in Otto Fuel II can be determined by one of two methods, either the nitrometer method or an HPLC method. The 2-NDPA content in Otto Fuel II can be determined by one of three methods, a spectrophotometric method (only for freshly manufactured propellant), a volumetric bromination method, or an HPLC method. Moisture content is determined by the Karl Fischer titration method. There is no specific method for di-*n*-butyl sebacate analysis, which is assumed to make the difference up to 100% after the other two ingredients and moisture have been quantified.

2-NDPA is made from *o*-chloronitrobenzene (OCNB) and aniline, but some of the raw material is carried over into the product and eventually ends up in Otto Fuel II, where 2-NDPA is used as a stabilizer. OCNB has been reported to cause tumors in male and female rats. A sample of Otto Fuel II was found to contain 0.00165% OCNB by HPLC analysis [380].

Safety Properties of Otto Fuel II

The desensitizer used in Otto Fuel II was intentionally insoluble in water. There was concern that if Otto Fuel II was spilled on a ship and the spill was washed away with sea water, the residue left behind after leaching out of a water-soluble desensitizer would be sensitive to detonation.

Although it has been proven that Otto Fuel can be made to detonate, the conditions and stimulus energy required are so extreme that it is considered a non-explosive, relatively low fire hazard for shipping and storage purposes. Otto Fuel II is routinely shipped by commercial carriers as a non-regulated item, Not Otherwise Indexed By Name (NOIBN).

Drop Weight Impact Sensitivity of Otto Fuel II

Drop weight impact sensitivity data reported for Otto Fuel II in the literature vary widely:

- 8.5 to 34.2 kg-cm (50% point) with a 2-kg mass in JANNAF (ASTM D-2540-70) Drop Weight Test
- 21 kg-cm (50% point) with a 2-kg mass in JANNAF (ASTM D-2540-70) Drop Weight Test
- 98 kg-cm (50% point) with a 2-kg mass in JANNAF (ASTM D-2540-70) Drop Weight Test

Adiabatic Compression Sensitivity of Otto Fuel II

Some of the early work by Princeton Combustion Research Laboratory (PCRL) on adiabatic compression sensitivity of liquid gun propellants included Otto Fuel II and NOS365 for comparison. In all these propellants, adiabatic compression sensitivity is dependent on the amount of pressurant gas saturation. In a liquid that is saturated with gas, the easy release of bubbles aids the propagation of low velocity detonations.

PCRL studied compression-ignition sensitivity of NOS365 and Otto Fuel II at pressure levels and pressure rise rates comparable to those of liquid propellant gun systems, particularly during the start-up phase of the ballistic cycle [381].

Most of the Navy-sponsored work on compression ignition sensitivity of liquid gun propellants conducted until 1986 used Otto Fuel II or NOS365 instead of XM46 or LP1845. See also [382].

Cap Sensitivity of Otto Fuel II

Otto Fuel II would not detonate when it was attempted to initiate it with a No. 8 blasting cap.

Shock Sensitivity with Unattenuated Booster Charges

Otto Fuel II can be detonated when a sufficiently strong booster charge is employed. The size of craters formed when detonating large boosters adjacent to 5-gal cans of Otto Fuel II were compared to the crater formed when the 5-gal pail was filled with water [383]:

- 75 lb Composition C-4 stacked on top of a 5-gal can of Otto Fuel II created a 6-ft diameter × 3-ft depth crater

- Five 5-gal cans, each containing 75lb C-4, surrounding a 5-gal can of Otto Fuel II created a 5-ft diameter × 3-ft depth crater
- 75lb C-4 stacked on top of a 5-gal. can of water created a 2-ft diameter × 1-ft depth crater.

A comparison of the crater sizes clearly indicated that the exploding Otto Fuel II made a substantial contribution to crater formation.

When Otto Fuel was formulated in the 1960s, it would sustain detonation in a schedule 40 pipe with an ID of 34.9 mm. More recently, shock loading experiments with 95.2 and 50.8 mm diameter, pressed (1.56 g/cm^3) pentolite donors were conducted on Otto Fuel II while heavily confined by thick-wall steel tubes with an ID of 50.6 mm [384]. When the donor shock was attenuated to the detonation pressure of Otto Fuel II, the larger donor produced a high-velocity detonation. The smaller donor produced a low-velocity detonation, indicating that recently produced Otto Fuel II was less detonable than it was in the 1960s. Other shock loading experiments using the smaller pentolite donor were conducted with less confinement from a thick-wall Lexan tube surrounding an aluminum tube with an ID of 25.4 mm. Reaction had failed within 100 mm for a shock loading near the detonation pressure of Otto Fuel II. When the aluminum tube was lined with bubble pack, which introduced an average but non-uniform porosity of 25%, violent reactions were attained for shock inputs ranging from 112 to 22 kbar.

Card Gap Sensitivity of Otto Fuel II

For tests in a slightly modified Naval Ordnance Laboratory (NOL) card gap test, since the critical diameter of Otto Fuel II is near 1.5 in., the usual card board containers of 1.44-in. diameter had to be replaced by a 2-in.-diameter × 1/4-in. wall thickness × 12-in. length pipe [383]. Table 48 shows the card gap data obtained at three temperatures for bubble-free Otto Fuel II and one value when carbon dioxide was bubbled through the liquid.

Table 48: Card gap sensitivity test data for Otto Fuel II.

Material	Temperature		
	−45 °F 230 K	80 °F 300 K	78 °C 351 K
Otto Fuel II	26.3 (0)	13.3 (0)	38.7 (0 to 13)
Otto Fuel II and CO ₂ bubbles		46.3 (26)	

2-in. diameter × 0.25-in. wall thickness × 12-in. length steel tube.

Numbers in parentheses are the number of cards at 1.44 in. in diameter (standard NOL test).

Data source: [383].

Accident History of Otto Fuel II

An accidental explosion involving a torpedo test vehicle occurred at a test facility in February 1995 [385]. The test vehicle was operating inside of a pressure vessel with 3-in.-thick walls when the incident occurred. The pressure vessel failed catastrophically, with the resulting high-speed fragments causing extensive damage to the reinforced concrete test cell. The 18-in.-thick cell walls and roof were completely perforated by the fragments. An investigation was performed to document the damage and assist the US Navy in determining the cause of the accident. This investigation included reconstruction of the pressure vessel and major portions of the test vehicle. Calculations were performed to estimate the source energy necessary to produce the observed amount of damage.

A summary paper [386] listed three Otto Fuel II explosions, including the description of one of the incidents:

Otto Fuel II fuel tank explosion during static testing; explosion in transfer pipeline in fire; explosion of propellant tank in fire finite propagation of low velocity detonation with heavy confinement or ullage (blast and fragment hazards similar to Class 1.1); minor explosion with lower confinement (near field fragment hazards)

but details on the other two incidents could not be obtained.

Handling of Otto Fuel II

The official document for the safe handling of Otto Fuel II on shore and shipboard is the *Technical Manual for Otto Fuel II – Safety, Storage, and Handling Instructions* [387]. This supersedes an older version [388].

Materials Compatibility with Otto Fuel II

Chapter 7 of Volume 3 of the CPIA Publ. 394, Hazards of Chemical Rockets and Propellants, Liquid propellants manual contains a detailed summary of handling instructions and compatible and incompatible materials of construction for Otto Fuel II [389].

Disposal of Otto Fuel II

During maintenance of torpedoes, large quantities of contaminated rinse water are created that need to be disposed of in a safe manner. Activated carbon has been found to be effective in removing Otto Fuel from water [390]. Preliminary pilot runs using Filtrasorb 400 show a low carbon cost per unit of wastewater treated as compared to the high cost of disposal by incineration. A carbon adsorption stage was planned to be used in the design of an Otto Fuel wastewater treatment plant several decades ago.

Toxicity of Otto Fuel II

The acute, short-term inhalation toxicity of Otto Fuel II is determined by its most volatile ingredient, 1,2-PGDN. The toxicity of PGDN by itself was discussed earlier in Section 9.3.1.1.5. The additional concern about the long-term toxicity of Otto Fuel

II stems from the carcinogenic properties of 2-NDPA and contaminants carried over from its manufacture. This is the reason why a significant effort was launched to find a non-carcinogenic replacement for 2-NDPA in Otto Fuel II and other solid propellant applications.

When Otto Fuel II was first introduced into the US arsenal, the sailors were warned that Otto Fuel II was toxic, and extrapolating from animal tests to humans was difficult. The problem was handled thus (quote [391]): "It has been estimated that ingestion of 2 ounces of Otto Fuel II would kill a man-sized rabbit." The tests resulted in a series of guidelines and recommendations for handling the material that were incorporated in the Safety and Handling Procedures OP 3368.

The toxicity of Otto Fuel II is described in S 6340-AA-MMA-0101 (as quoted in MIL-O-82672A). The LD50 (oral) is 332 mg/kg.

The CPIA/M4 Unit 35 manual stated "Carcinogenicity: none of the components of Otto Fuel are suspected carcinogens," but it must be pointed out that not the original component, but the **nitrosamine** that forms during storage, aging, and gradual stabilizer degradation of 2-NDPA is indeed a carcinogen.

Additional information on the toxicity of Otto Fuel II and its components is available from several US government reports [392]. The toxicological profile of Otto Fuel II and its components published by the Agency for Toxic Substances and Disease Registry (ATSDR) in 1995 is a very thorough compilation of toxicity data and recommended safe handling practices for Otto Fuel II [393].

Environmental Effects of Otto Fuel II

Environmental Fate. Otto Fuel is a chemically stable liquid that is insoluble in water. Its transport in the environment in water would be expected to be very limited, due to this hydrophobicity. In a land spill, Otto Fuel would probably absorb into clays and biological particles rather than leach downstream. In a surface water spill, Otto Fuel would be adsorbed into bottom sediments. In small concentrations, Otto Fuel should be biodegradable both in surface water and in soil. In the environment, a simple nitrate ester would be biodegradable. However, the other constituents of Otto Fuel may cause it to be somewhat more persistent.

The factor that controls the rate of buildup of Otto Fuel vapor in the atmosphere of any environment in which Otto Fuel II is spilled is the rate of evaporation of material from the spill. To obtain more information on the quantitative aspects of the problem, the evaporation rate of Otto Fuel II at 298–300 K (25–27 °C) was determined by weight loss measurements in a nitrogen atmosphere [394]. After an initial period of 3–4 h, the evaporation rate was found to be $0.18 \text{ g h}^{-1} \text{ ft}^{-2}$ of the spill. An initially higher weight loss was attributed in part to water that was dissolved in Otto Fuel II and in part to the presence of a volatile impurity that could not be removed by drying the liquid with calcium sulfate. The observed evaporation rate was in good agreement with the rate of $0.52 \text{ g h}^{-1} \text{ ft}^{-2}$ reported for PGDN at 308 K (35 °C) and with the rate of $0.135 \text{ g h}^{-1} \text{ ft}^{-2}$ calculated for PGDN at 298 K (25 °C) using Langmuir's method of calcu-

lating the evaporation rate of liquids into a stagnant atmosphere. A new technique, based on differential pulse polarography, was developed for the quantitation of the rate of PGDN diffusion in sea water. This technique was used to follow the diffusion of Otto Fuel II through a stagnant layer of sea water. Under favorable circumstances (i.e., complete coverage, no agitation), the covering of an Otto Fuel II spill with sea water reduced the evaporation rate by a factor of 1/10000.

PGDN spilled on the ground and soaking into soil will eventually disappear by biodegradation [395, 396].

9.3.1.1.8 Other Propellant Mixtures with 1,2-Propylene Glycol Dinitrate

Torpedo fuels similar to Otto Fuel II have been used by other navies [397].

9.3.1.2 1,3-Propylene Glycol Dinitrate

1,3-Propylene glycol dinitrate, 1,3-propanediol dinitrate, 1,3-dinitroxypropane, trimethylene glycol dinitrate, $\text{O}_2\text{NO}-\text{CH}_2-\text{CH}_2-\text{CH}_2-\text{ONO}_2$, $\text{C}_3\text{H}_6\text{N}_2\text{O}_6$, PGDN, CAS RN 3457-90-7, is a colorless oil. Like GTN, it can be used as a gel-forming (gelatinizing) solvent for nitrocellulose. The physical properties of 1,3-PGDN are summarized in Table 49.

1,3-PGDN is less volatile than EGDN but more volatile than GTN. It is less impact-sensitive than GTN and more stable during storage at high environmental temperatures. In the BAM impact sensitivity test apparatus, no reaction could be observed at energies up to 20 N m.

In the lead block test, detonation of 1,3-PGDN caused an enlargement of the cavity by $540 \text{ cm}^3/10 \text{ g}$, which is a very high number.

Table 49: Physical properties of 1,3-PGDN.

9.4 Glycerol Trinitrate (Nitroglycerin)

Glycerol trinitrate, also known as $\text{C}_3\text{H}_5(\text{ONO}_2)_3$, $\text{C}_3\text{H}_5\text{N}_3\text{O}_9$, nitroglycerin, nitroglycerine, NG, glycerin trinitrate, GTN, 1,2,3-propanetriol trinitrate; trinitrate, propane-1,2,3-triyl; 1,2,3-glyceryl trinitrate, CAS RN [55-63-0], is a pale yellow liquid explosive with a legendarily high sensitivity to impact and other stimuli. The common name is *nitroglycerin* (abbreviated as NG), but that is a misnomer and chemically incorrect since this is not a *nitro* compound. We are slowly shifting to the correct name *glycerol trinitrate* and hope that readers will go along on this new trend. Glycerin trinitrate is also sometimes used as the name for this compound.

Alfred Nobel's invention that GTN can be desensitized by absorbing it on kieselguhr or porous pumice led to the widespread use of dynamite and enriched Nobel's wealth and worldwide fame. GTN can be gelled with various additives (including nitrocellulose) to form blasting gelatin and propellants like cordite and ballistite, precursors for modern double-base propellants.

GTN is one of the few organic compounds with a positive oxygen balance. The oxygen balance for combustion to CO_2 is +3.5%. It contains more oxygen than is needed to burn all carbon to carbon dioxide and all hydrogen to water.

9.4.1 Production of Glycerol Trinitrate

GTN is produced in large quantities industrially by the nitration of glycerol with nitrating acid, a mixture of concentrated nitric acid and sulfuric acid. Once produced, it is usually consumed as a captive product by secondary processes on site and is not shipped as such (except in thriller movies). The literature on the safe production of GTN is voluminous and cannot be included in detail in this book. References to a few typical publications may suffice [398].

The use of dinitrogen pentoxide instead of mixed acid as the nitrating agent avoids the problem of having to dispose of spent acid [399].

Sometimes glycerol is not nitrated all the way to GTN, but it may be desirable to stop the nitration at the dinitrate level to make glycerol dinitrate (GDN), an intermediate for the synthesis of GLYN that is used to make an energetic binder. To optimize the yield of dinitrate and prevent the last step from leading to trinitrate, it is necessary to better understand the kinetics of the nitration process. Therefore, the equilibrium constants of seven sequential-parallel reactions of conversion of glycerol into GTN in HNO_3 were measured [400]. The effect of the acidity of the medium on the equilibrium nitration constants was correlated with processes of protonation of glycerol and its nitrates. The equilibrium nitration constants were higher for primary hydroxides than for secondary hydroxides, and they decreased in both series in going from glycerol to its dinitrates.

Glycerol can be treated to make 1,3-GDN as an intermediate product to produce polyGLYN. Nitration of glycerol to 1,3-dinitroglycerin was studied in the temperature

range 283–303 K (10–30 °C), a molar ratio of nitric acid to glycerol 1/1 to 7/1, and nitric acid concentration of 69% [401]. Seven reaction kinetic rate terms represented the reactions that occurred in the nitration of glycerol. The position of the hydroxyl group in the glycerol molecule caused different reaction rates. The primary hydroxyl group was more reactive than the secondary hydroxyl group.

The nitration of glycerol was modeled by fitting the kinetic model with six parameters, the rate constant at an average temperature and the activation energy [402]. The reaction rate was assumed to be governed by three reactions: the formation of **(1)** GMN, **(2)** GDN, and **(3)** GTN.

9.4.2 Physical Properties of Glycerol Trinitrate

The physical properties of GTN at a fixed temperature (usually 298 K) are summarized in Table 50. More detailed data, in particular the variation of key physical properties over a wider range of temperatures, are discussed in individual sections below. Additional properties of GTN are discussed in [403–405].

9.4.2.1 Freezing Point and Melting Point of Glycerol Trinitrate

The freezing point of GTN in its stable modification is 286 K (+13 °C). Early in the history of NG, it was discovered that liquid NG could be “desensitized” by cooling it to about 278 to 283 K (5 to 10 °C = 40 to 50 °F). At this temperature NG freezes, contracting upon solidification. However, thawing it out can be extremely tricky, especially if impurities are present or if the rate of warming is too rapid. One of the methods to avoid freezing is to add freezing-point-depressing additives that are compatible with GTN. These additives are usually nitrate esters of similar aliphatic polyols.

It is difficult to explain why there are two different versions of GTN that differ in stability and freezing points. GTN may crystallize in two allotropic modifications, a metastable, labile form and a stable form, of which only the first can be converted into the other. This conversion occurs readily, so that there is a monotropic allotropy. Chemically pure GTN is more difficult to crystallize, but it always crystallizes in the labile form. Less pure NG, on the other hand, freezes more readily but mostly in the stable form. On contact with a crystal of the stable form, the labile-form liquid converts to the stable form immediately, or, without such contact, after a certain time at an optimum temperature for the conversion to take place. Thus, any nitrate-ester-plasticized propellant that has been embrittling for some time will contain the stable, higher freezing and melting crystal form because of this spontaneous conversion.

Most published data on alkyl nitrate freezing points were done by cooling the sample, but most alkyl nitrates tend to supercool and the freezing points vary considerably. Also, some alkyl nitrates freeze to a metastable form that is not identical with the stable form formed during long-term storage. It would be more accurate to measure the melting points of frozen alkyl nitrates. The melting points of five different frozen nitrate ester samples were determined by visual observation and in a low-temperature DSC [407]. All samples were preconditioned to 230 K (−43 °C) and stored at that temperature. Table 51 is a summary of melting points (both visually observed and DSC measurement) of GTN in comparison to four other nitrate esters that are also commonly used as plasticizers in double-base propellants.

Many alkyl nitrates and polynitrates have a tendency to supercool and do not crystallize voluntarily. Therefore, it is difficult to determine a freezing point by cooling a liquid sample. A systematic study was conducted of four nitrate esters, GTN, BTTN, TMETN, and TEGDN, which are used to better control the crystallization phenomena of plasticizers in propellants [406]. The tests were done to determine the melting characteristics of these four frozen compounds and to compare new measurements to the old data in the literature, which were sometimes incomplete or unreliable. The influence of temperature on the rate of crystal growth was studied for four nitric esters by photographic observation, while nucleation was specifically considered for GTN and TMETN, two nitrate esters that exist in allotropic modifications and may form two crystallographic different varieties, depending on the mode of nitration and the tem-

perature/time history. The melting point of frozen unstable GTN was 276 K (+3 °C), the melting point of the stable form was 288 K (15 °C), and the heat of fusion was 21.85 kJ/mol = 96 J/g = 5.22 kcal/mol = 23 cal/g. The heat of fusion of GTN was the highest among the four alkyl nitrates tested. If GTN is supercooled and seed crystals are inserted into the liquid to induce solidification, different forms of GTN are obtained depending on the type of seed crystal inserted. Seed crystals of potassium nitrate gave only the metastable form, but seed crystals of sodium salicylate gave a mixture of both allotropes with more of the stable form. If a sample of supercooled GTN is conditioned at 233 K (−40 °C) for 3 h to 8 weeks, and samples are taken and seeded to induce crystallization, initially the solidification exotherm occurs only at 277–278 K (4–5 °C), but with increasing age of the sample the exotherm at 277–278 K disappears and is replaced by one at 288 K (15 °C). The rate of crystallization of supercooled GTN was measured as a function of the preconditioning temperature between 233 and 283 K. Liquid GTN samples that have been aged at different temperatures for 2 h and then induced to crystallize will crystallize the fastest if aged at 268 K (−5 °C).

9.4.2.2 Vapor Pressure of Glycerol Trinitrate

The vapor pressure of GTN between 400 and 524 K can be calculated from the Antoine equation

$$\log_{10}(P) = 4.07588 - (2508.448 / (T - 39.235))$$

where P is the vapor pressure in bar and T is the temperature in kelvin. Other vapor pressure data for GTN are in Table 52, 53, and 54. See also [294, 408].

Table 52: Vapor pressure of GTN.

Temperature			Vapor pressure		
K	°C	°F	Pa	millibar	mm Hg

Data source: [15]

A comparison of several papers reporting the vapor pressure of NG illustrated in Figure 29 showed general satisfactory agreement among data from different authors, except that the Clausius-Clapeyron fit of the data by John [294] and Crater [15] had to be excluded because they were outliers [295]. The Clausius-Clapeyron fit of the data led to the equation

$$\log P = A - B/T = 11.88 - 4529/T$$

where P is the vapor pressure in mmHg and T is the temperature in kelvin for the temperature range 286–356 K (13–93 °C). The vapor pressure at 298 K was extrapolated to 4.81×10^{-4} mmHg. The heat of evaporation is 86.7 kJ/mol. In light of its importance in the explosive industry and known health effects, surprisingly no recent papers have

Figure 29: Vapor pressure of GTN. (Republished and modified from [295], with permission of © 2012 John Wiley Sons – Books; permission conveyed through Copyright Clearance Center Inc.)

dealt with the room temperature vapor pressure of NG. NG freezes at 285.9 K (12.8 °C), but no data on the vapor pressure of solid NG could be found.

9.4.2.3 Optical Properties of Glycerol Trinitrate

An IR spectrum of GTN is shown in Figure 30. The self-association of GTN in the liquid state and in tetrachloroethane solution (at various dilutions) was studied by IR spectra, especially focusing on the vibrations of the $-\text{NO}_2$, $-\text{ONO}_2$, and C–H bonds [409]. The formation of dimers and higher aggregates changes with dilution. As in the crystal state, associations appear to take place within the NO_2 groups by interaction between an O atom of one of the ester groups and the N atom of a second ester group. Hydrogen-bonded associations appeared only in concentrated and bulk solutions and

Figure 30: IR spectrum of GTN. (From [296].)

were less stable. In liquid GTN at room temperature, the concentrations of monomer and dimer are small, with tetramer and trimer dominating.

In the near-IR spectra from 1000 to 2500 nm of GTN and other explosives, particularly intense and complex were the bands corresponding to the first combination region (2500–1900 nm) and first overtone stretching mode of C–H and N–H bonds (1750–1450 nm) [410].

The Raman spectra of GTN and glycerol mononitrate (GMN) were described in [25] and [26].

9.4.2.4 Thermodynamic Properties of Glycerol Trinitrate

The thermodynamic properties of GTN are summarized in Table 55.

The heat evolved during the production of GTN by the nitration of glycerol must be carefully managed to prevent runaway reactions in the nitration vessel. The real

enthalpies of seven sequential-parallel reactions of glycerol nitration into glycerol mono-, di-, and trinitrate were found by the combination of the heats of the reactions obtained by the thermochemical method and with the equation for the isobar of the chemical reaction, and the standard enthalpies of formation of glycerol nitrates were calculated with them [411, 414, 415]. The difference in the enthalpies of nitration with respect to different positions in glycerol and its nitrates basically determines the difference in the corresponding equilibrium constants of the nitration reactions.

9.4.2.5 Molecular Structure of Glycerol Trinitrate

Proton magnetic resonance (PMR, ¹H NMR) spectra at a frequency of 294 MHz for glycerol and its mono-, di-, and trinitrates have been measured in nitric and sulfuric acids and in deuteroacetonitrile [416]. The conformational composition weakly depends on the medium, temperature, and number of nitrate groups in the molecule. Conformers with CH₂ and OH (or ONO₂) located in a *trans* position have a certain preference.

9.4.3 Chemical Properties of Glycerol Trinitrate

9.4.3.1 Thermal Decomposition of Glycerol Trinitrate

9.4.3.1.1 Experimental Studies of Thermal Decomposition of Glycerol Trinitrate

GTN decomposes in the vapor phase at 403–423 K (130–150 °C) at a rate proportional to its vapor pressure, and the rate decreases with time according to first-order reaction kinetics [417]. In the presence of liquid-phase GTN, the rate of gas formation in the same interval of temperature is smaller; it gradually increases with time and depends on the pressure of the decomposition products whether or not they are vented. When the decomposition reaches a certain critical pressure of the trapped decomposition products, the rate of gas formation increases proportionally to the square of the pressure. The critical pressure is ~27 kPa at 373 K (~200 mm Hg at 100 °C). The sharp increase in the rate is due to the effect of the pressure on the accumulation of gaseous decomposition products (H₂O and HNO₃) in the liquid phase. The presence of these products accelerates hydrolytic and chemical reactions, whose rates are much faster than the rate of initial thermal decomposition of pure GTN. If all the decomposition products remain trapped in the liquid phase, the accelerated runaway reaction rate of the decomposition of GTN begins at 373 K (100 °C) after ~9 h. Accelerated gas formation is associated mainly with the accumulation of HNO₃. Neutralization of the acid with Na₂CO₃ eliminated the acceleration. The time for the onset of acceleration was considerably shortened in the presence of HNO₃ and H₂O.

The thermal decomposition of NG was investigated in the vapor and liquid states over a temperature range of 388–433 K (115–160 °C) [418]. Above 413 K (140 °C) the decomposition in the vapor phase was first order, but in the liquid phase the order was only approximately first order. At all temperatures the rates were found to vary markedly with the ratio of the mass of NG to the volume of the reactor, indicating wall effects and free radical chain termination. Below 413 K (140 °C) the decomposition

was autocatalytic with free HNO_3 catalyzing the reaction. A mechanism was proposed for the vapor-phase reaction that was in agreement with the experimental data.

The slow thermal decomposition of GTN at 383 K (110 °C) was examined by GC analysis of gas evolution and showed mostly CO_2 but no free NO_2 [419]. NO was seen only during the first hour of the test. Time-resolved IR spectrophotometry for 72 h at 383 K showed that the O— NO_2 band had diminished, but the C=O bands had increased due to evolution of ketones and aldehydes. GC/MS identified N_2 , CO_2 , HCHO, HCOCOH , HCOOH , HOCH_2COOH , and HOCCOOH as decomposition products.

GTN samples were mixed with different organic and inorganic compounds that it might encounter as contaminants or propellant ingredients and investigated by heat flow calorimetry [420]. The timing and severeness of the autocatalytic reaction were very dependent on the nature and amount of the added contact material. NMR analyses of GTN and its decomposition products proved that the main reaction can be characterized by a homolytic split of the nitrate ester bond, preferably in the center position. The distribution of reaction products (1,3-dinitroglycerin and 1,2-dinitroglycerin) and the further decomposition products (dinitroglycerol carboxylic acid, mononitroglycerol carboxylic acids) was dependent on neither the structure nor the amount of contact material, nor was it a function of the reaction time. But the severeness of the decomposition reaction was dependent on the type of additive. Some contact materials changed the mechanism of the decomposition reaction. The addition of basic substances led to an increase of ester bond hydrolysis. The addition of radical scavengers (4-methoxyphenol) effectively prevented the formation of nitroglycerol carboxylic acids. As mentioned in other publications, an increase of diphenylamine (DPA) to over 1% did not result in a stabilizing effect. Other stabilizers (2-NDPA, N-NO-DPA) showed a much better stabilizing effect in binary mixtures. Also, non-reactive bases like carbonates stabilized GTN very well. Compared with GTN, other nitrate esters (ethyl nitrate, BBTN) were much more stable.

A dual-shutter ion mobility spectrometer operating at atmospheric pressure and interfaced to a gas chromatograph for sample introduction has been used to study the reaction of Cl^- with nitrate esters in explosive vapor-detecting mass spectrometers [421]. Of particular interest was an investigation of the formation of NO_3^- from the reaction of the Cl^- with GTN. The adduct $\text{GTN}\cdot\text{Cl}^-$ together with NO_3^- and $\text{GTN}\cdot\text{NO}_3^-$ compose the mobility mass spectrum. Over the temperature range 374–395 K (111–122 °C), $\text{GTN}\cdot\text{NO}_3^-$ was stable, but $\text{GTN}\cdot\text{Cl}^-$ decomposed to NO_3^- and 1,2-dinitro-3-chloropropane. The activation energy and preexponential factor for this first-order decomposition was $80 \pm 3 \text{ kJ/mol}$ and $1.3 \times 10^{12} \text{ s}^{-1}$, respectively.

9.4.3.1.2 Computations Relating to Thermal Decomposition of Glycerol Trinitrate

DFT calculations were performed to determine various decomposition channels for GTN [422]. For the unimolecular decomposition mechanism of GTN, two main mechanisms were found: **(1)** homolytic cleavage of O— NO_2 to form $\cdot\text{NO}_2$ and $\text{CH}_2\text{ONO}_2\text{CHONO}_2\text{CH}_2\text{O}\cdot$, which subsequently decomposes to form $\cdot\text{CHO}$, $\cdot\text{NO}_2$, and $2\text{CH}_2\text{O}$; and **(2)** successive HONO eliminations to form HONO and CHO—CO—CHO ,

which subsequently decomposes to form $\text{CH}_2\text{O} + 2\text{CO}_2$ and $\cdot\text{CHO} + \text{CO}$. The former channel has slightly lower activation energy than the latter one. The calculated rate constants of the initial process of the two decomposition channels showed that the $\text{O}-\text{NO}_2$ cleavage pathway occurred more easily than the HONO elimination pathway.

9.4.3.2 Reactions of Glycerol Trinitrate with Inorganic Reactants

The hydrolysis of GTN may be an undesirable reaction during storage of GTN-containing propellants in moist areas, or it may be used with advantage in the decontamination of GTN-containing wastewaters from the production or demilitarization of GTN and GTN-containing propellants. The hydrolysis is aided by alkaline conditions.

The reaction between GTN and NaOH in aqueous solution at various mol ratios was followed UV spectrophotometrically and the loss of GTN determined polarographically after several hours of reaction time [423]. The initial reaction of GTN occurred by an α -hydrogen elimination with the formation of a carbonyl and nitrite ion NO_2^- . A slow reaction with the formation of NO_2^- occurred concurrently with α -H elimination.

9.4.3.3 Analysis of Glycerol Trinitrate

9.4.3.3.1 Assay and Purity Control of Glycerol Trinitrate

The analytical methods for determination of assay and contaminants in GTN are described as part of Military Specification MIL-N-246B.

GDN contamination in GTN can be separated by thin-layer chromatography and identified by IR [424]. The main impurity was glycerol 1,3-dinitrate, CAS RN [623-87-0], with only traces of glycerol 1,2-dinitrate, CAS RN [621-65-8].

9.4.3.3.2 Trace Detection of Glycerol Trinitrate in Workroom Air

As it turns out, workplace exposure to GTN either by inhalation or skin resorption occurs not only in the explosives and propellant industry, but also in pharmaceutical companies where GTN is formulated into tablets and skin patches as a medicine for lowering acutely high blood pressure in human patients. Beyond that, detection of GTN and other explosive nitrate esters in improvised explosive devices suspected to be used by terrorists is an important task to assure security of the general public, in particular for the safety of air travel. The industry has developed very sensitive instruments to detect traces of explosive vapors. Instruments that were initially developed for security forces can now be used beneficially to monitor workroom air in a controlled environment. Similar methods can now be used to monitor workroom air in propellant factories and munitions storage magazines.

Liquid chromatography-mass spectrometry (LC-MS) with electrospray ionization (ESI) and atmospheric pressure chemical ionization (APCI) in negative-ion mode were investigated for the analyses of three widely used nitrate ester explosives, PETN, GTN, and EGDN, as well as six additional nitrate esters [425]. In ESI, ammonium nitrate and ammonium chloride promote the formation of characteristic adduct ions of the

respective nitrate esters. In APCI, chlorinated agents, dichloromethane, chloroform, carbon tetrachloride, and ammonium chloride, are used, forming more easily ionizable chloride attachment adduct ions. For comparison, three authentic forensic samples, Booster DYN0, Semtex, and Smokeless Powder, were analyzed to demonstrate the validity of the developed LC-MS methods.

The two closely related ion spectrometric methods used in explosive detection and analysis include MS and ion mobility spectrometry [426]. The four fundamental requirements: speed, selectivity, sensitivity, and ease of sampling can be fulfilled with each of these methods.

The recommended analysis methods for analysis of GTN (and EGDN) in workroom air are NIOSH 2507 [427, 428] and OSHA43 [429]. In these methods, which are suitable for a concentration range 0.6 to 3.2 mg/m³ in a 15-L air sample, the analyte is first adsorbed from the air on a solid sorbent Tenax-filled tube and then extracted with ethanol and analyzed by GC.

9.4.3.3.3 Trace Detection of Glycerol Trinitrate in Body Fluids

The desirable ability to monitor GTN exposure of workers in the workplace by taking blood or urine samples at the end of the work shift and the establishment of a BEI with a maximum allowed GTN concentration depends on the availability of sensitive analytical methods. The occupational health aspects of BEI will be discussed subsequently in Section 9.4.4. The current section deals only with analytical instrumentation. In addition to monitoring GTN in blood or urine of propellant factory workers and military personnel, the same methods will also help physicians to select a safe dosage of GTN pills or dermal patches for patients with high blood pressure. Patients may metabolize GTN at different rates, so the maintenance dosage must be adjusted individually.

A sensitive method for the quantitative determination of GTN in human plasma was developed in which GTN and an internal standard (BTTN) were first extracted from plasma with *n*-pentane [430]. The extracts were analyzed by GC-MS using fused silica capillary columns and electron capture negative ion chemical ionization. The quantitation limit of the method was about 50 pg/mL. Linear calibration curves were obtained in a range of 50–1600 pg/mL. Precision at the level of 100 pg/mL was 4%. A similar method used *n*-hexane instead of pentane for extraction, with identical results [431].

A method for the quantitative determination of GTN in human plasma by GC-MS was developed that added (¹⁵N)GTN as internal standard, extracted with a mixture of pentane and methyl acetate, purified by partition between, first, the extraction solvent and a mixture of acetonitrile and water (60:40) and, secondly, the resultant aqueous phase and benzene [432]. The solvent was evaporated to a small volume before injection. The fragment ions at *m/z* 46 and 47 were monitored for the measurement of the [NO₂]⁺ and [¹⁵NO₂]⁺ ions using electron impact ionization. The mean recovery in blind plasma samples spiked with amounts in the concentration range 0.35–3.52 nmol/L was 97.4% (*n* = 58). Concentrations in plasma could be estimated down to

about 0.2 nmol/L (50 pg/mL). Recovery of doped samples in duplicate determinations in the range 0.5–1.96 nmol/L was 99.4% ($\pm 6.0\%$ relative) ($n = 80$).

GTN is metabolized in the body to glycerol 1-nitrate and glycerol 2-nitrate, which can be determined by a GC method that is suitable for a variety of biological samples and can detect nitrates down to the low nanogram range [433]. An extract of the sample to be analyzed was treated with phenylboronic acid. The GMNs rapidly formed cyclic boronate derivatives, with five- and six-membered rings, respectively, which could then be separated by GC and detected by an electron-capture detector.

A sensitive GC/electron-capture detection method for the simultaneous determination of GTN and its dinitrate metabolites (1,2-GDN and 1,3-GDN) was developed in which human plasma samples (1 mL) spiked with 2,6-dinitrotoluene as an internal standard were extracted with 10 mL of a methylene chloride/pentane mixture (3:7 v/v) [434]. The limits of detection by this method for GTN, 1,2-GDN, and 1,3-GDN in plasma were 0.025, 0.1, and 0.1 ng/mL, respectively. A similar method that also separated the three compounds can be found in [435].

A sensitive, specific capillary GC-electron-capture detection method for the simultaneous determination of GTN, 1,2-GDN, and 1,3-GDN and 1- and 2-glyceryl mononitrate (1-GMN and 2-GMN, respectively) with a minimum quantifiable concentration for GTN, GDNs, and GMNs of 0.4 ng/mL in plasma, with extraction recoveries for GMNs 76% and for GTN and the GDNs 95% was developed to be used in pharmacokinetic studies [436]. Following controlled addition of GTN to human blood, the ratio of 1,2-GDN to 1,3-GDN maximum concentrations was ca. 7:1, reflecting preferential denitration of the GTN molecule at the primary positions, while the ratio of 2-GMN to 1-GMN in this system was ca. 6:1, representing a highly selective if not specific primary denitration of the 1,2-GDN molecule. Following the intravenous administration of 1,2-GDN to five healthy male volunteers, 2-GMN/1-GMN ratios averaged 8.8:1, representing a highly selective but not specific formation of 2-GMN from the 1,2-GDN molecule. The assay will find utility in *in vitro* studies attempting to address the molecular pharmacology of GTN and its metabolites and in *in vivo* clinical pharmacology studies attempting to address the relationship between pharmacokinetics of GTN and its metabolites.

A method for the quantitative analysis of NG and its dinitrate metabolites (1,2- and 1,3-GDN) in urine would first extract the analytes by liquid-liquid extraction and then analyze them by GC-MS with negative ion chemical ionization [437]. The method was able to detect 0.3 nmol/L for all analytes and was linear over the range of at least 0–44 nmol/L. The method was then used to determine metabolite levels in a subject using NG therapeutically for the treatment of angina. Metabolites were stable in urine for at least 6 d at room temperature.

An HPLC-MS method for the simultaneous determination of GTN and its active metabolites 1,2-GDN and 1,3-GDN for a range of GTN and GDN concentrations of 0.5–15 ng/mL also used BTTN as an internal standard [438]. The lower limit of quantification was about 0.01 ng on column. An application of this method was illustrated during *in vitro* studies of GTN metabolism in cultured media and human vascular smooth

muscle cells at 310 K (37 °C). With this method, the degradation half-life of GTN in rat plasma at 310 K (37 °C) was 26.8 ± 1.8 min, consistent with previous values obtained using GC instead of HPLC.

GTN, and its two main metabolites, 1,2-GDN, CAS RN [621-65-8], and 1,3-GDN, CAS RN [623-87-0], in human plasma can be analyzed using a capillary GC method with an electron-capture detector [439]. Linear calibrations were obtained for 1,3-GDN from 0.14 to 3 ng/mL, for 1,2-GDN from 0.06 to 6 ng/mL, and for GTN from 0.01 to 0.3 ng/mL in plasma samples. The calculated limits of quantification values for GTN, 1,2-GDN, and 1,3-GDN were 0.03, 0.2, and 0.15 ng/mL, respectively.

Besides 1,2-GDN, 1,3-GDN, and GMN, the nitration product 3-nitrotyrosine has been observed in human plasma or urine as a result of GTN exposure and can be used as a marker in a BEI for GTN exposure.

9.4.3.3.4 Analysis of Glycerol Trinitrate Mixtures

In many applications GTN is not used in the pure state but is desensitized by the addition of desensitizers and is stabilized by the addition of stabilizers. The contents of diluents and stabilizers must be carefully controlled by chemical analysis to maintain safe conditions. The composition of GTN/BTTN mixtures can be determined by HPLC [440].

9.4.3.4 Specifications for Glycerol Trinitrate

The purity requirements for GTN are specified in MIL-N-246B, which also contains the analytical methods recommended for the quality control of GTN [441]. This specification covers two types of NG for use in propellants: Type I uses Grade B glycerol, and Type II uses partially polymerized glycerol (diglycerin). For Type I, the nitrogen content must be 18.4% minimum. For Type II, the nitrogen content must be 17.8–17.9%. When subjected to a 355.3 K (82.2 °C) heat test, the GTN will not change the color of the standard potassium iodide starch paper in less than 10 min.

9.4.4 Toxicity of Glycerol Trinitrate

At room temperature, GTN is an oily, colorless to pale yellow liquid with a sweet, burning taste. GTN has very toxic effects following inhalation, skin contact, or ingestion [442]. It is a most useful drug to treat angina pectoris, congestive heart failure (particularly acute myocardial infarction), and hypertension. In industrial situations, inhalation of vapor by airways and skin contact are potential exposure routes. Data concerning GTN concentrations in workplace air date from the second half of the 20th century. Concentrations measured at that time in workplaces were 0.1–4.0 mg/m³. Data on human exposure indicated that blood vessel dilation is a critical effect of GTN exposure and is its major effect when used as medication. Headache, blood pressure decrease, and nausea are GTN exposure symptoms that result from blood vessel dilation. In occupational settings, these symptoms were observed in workers exposed to 0.3–4.0 mg/m³ GTN. Similar symptoms were noted in persons following dermal exposure

(patches releasing 5 mg GTN). The absorbed dose corresponds to a GTN air concentration of 0.5 mg/m^3 , assuming lung ventilation is 10 m^3 in an 8-h shift. Higher concentrations could induce depression, methemoglobinemia, and cyanosis. After decreasing workplace air GTN concentrations to 0.1 mg/m^3 (0.01 ppm), no adverse effects were observed in workers. There were no reliable data on increased human risks of coronary and cerebrovascular diseases induced by GTN. Study results were conflicting. Some cohort studies suggested the incidence of these diseases is generated by EGDN, often used together with GTN. There was also a lack of data on repeated inhalation exposure of experimental animals. In animals, methemoglobinemia and toxic liver and testes effects were observed following intragastric GTN administration in high doses. Rat and dog studies helped determine the value of no observed adverse effect level for GTN in the dose range of $25\text{--}40 \text{ mg kg}^{-1} \text{ d}^{-1}$ for systemic effects, including reproductive toxicity, which corresponded to much higher GTN concentrations in air than concentrations inducing toxic effects in humans. *In vitro* study results of its mutagenic effect have not shown strong or even slight mutagenic effects; all *in vitro* studies of mutagenic effect produced negative results. The International Agency for Research on Cancer has not classified the carcinogenicity of GTN to humans. In Germany, GTN has been categorized into Group 3B for carcinogenicity. The Scientific Committee on Occupational Exposure Limits classified GTN as a carcinogenic compound (Group C), a genotoxic carcinogen for which it is possible to set an admissible practical value based on existing data. There are no data concerning the GTN effect on the human reproductive system. In a three-generation reproductive toxicity study in rats, the F0 generation showed no effect of GTN on reproduction. Major reproduction disorders were observed in the F1 group administered the highest GTN dose, which was associated with inhibition of spermatogenesis and significant decrease in testes mass. Other studies revealed no effect of GTN on reproduction. In Germany GTN was categorized in Group C, a substance not expected to damage embryos and fetuses if the Maximum Allowable Concentration (MAC) value is strictly observed. GTN enters the body through airways and skin; its through-skin absorption capacity in humans is 68–76%. There are no data concerning airway GTN absorption. Results of occupational studies showing no adverse effects of GTN exposure at concentrations 0.095 mg/m^3 (0.01 ppm) have been suggested as the basis for setting GTN MAC values. It has been suggested to adopt a 0.095 mg/m^3 (0.01 ppm) GTN concentration as MAC value. It has been suggested that a 0.19 mg/m^3 (0.02 ppm) concentration be adopted as STEL, since irritation effects were observed in workers exposed to $\sim 0.3 \text{ mg/m}^3$ GTN.

9.4.4.1 Animal Exposure Tests with Glycerol Trinitrate

In experimental animal exposure tests, the LD₅₀ was $1888 \pm 76 \text{ mg/kg}$ (mice, male, intragastric), LD₅₀: $1055 \pm 63 \text{ mg/kg}$ (mice, female, intragastric), LD₅₀: $822 \pm 54 \text{ mg/kg}$ (rats, male, intragastric) and LD₅₀: $844 \pm 61 \text{ mg/kg}$ (rats, female, intragastric). GTN is an experimental teratogen.

The rate of resorption of GTN through the skin was measured in rats [443]. From a gelled explosive that contained 93% GTN and 7% NC, the GTN was resorbed at a rate

of $0.85 \text{ mg cm}^{-2} \text{ h}^{-1}$, which was much slower than the rate of resorption of EGDN that had been tested in earlier experiments.

9.4.4.2 Mutagenicity of Glycerol Trinitrate

GTN is mutagenic in the Ames test with *S. typhimurium* strain TA1535. GTN increased the number of His⁺ revertants to a maximum of four times over background at a GTN dose of $5 \mu\text{mol/plate}$ [444]. Hamster liver S9 enzyme depressed the toxicity of high GTN doses but increased the maximum number of revertants to five times over background at $10 \mu\text{mol/plate}$. GTN did not cause significant reversion in any of the six other *S. typhimurium* strains tested, although signs of toxicity were observed. Therefore, the mutagenicity of GTN was manifest only in the repair-deficient strain, which is responsive to single base changes. A similar mutational spectrum was seen previously with nitric oxide (NO)-releasing chemicals. This suggested that NO, which can be derived from GTN via metabolic reduction, may be responsible for GTN's mutagenic action.

9.4.4.3 Carcinogenicity of Glycerol Trinitrate

GTN was reported to induce hepatocellular carcinoma (HCC) in rats after prolonged feeding. Additional experiments were undertaken to evaluate the histogenesis and molecular biology of these tumors and the possible role of nitric oxide (NO), a GTN metabolite, in their development [445]. Male F344 rats received a single intragastric (IG) intubation of GTN (1.2 g/kg) at 6 weeks of age and/or a diet containing 1% GTN from 8 weeks of age until necropsy, i.e., for up to 78 weeks. Some animals were subjected to 2/3 partial hepatectomy at 9 weeks of age. Five sequential sacrifices (14, 32, 52, 78, and 84 weeks of age) were performed. No liver tumors developed in control rats or in rats that received GTN only by a single IG intubation. Preneoplastic foci, mainly of clear cell and mixed cell type (identified as positive for glutathione S-transferase placental form), were found from 14 weeks of age in rats receiving GTN in the diet. HCCs were seen beginning at 78 weeks of age, but only in rats receiving dietary GTN. Incidence of HCC in the latter animals was 50–75%. Most HCCs were well differentiated. The fact that tumors arose only on prolonged feeding of this potentially bioactive agent at massive doses seems consistent with a more complex mechanism involving multiple (i.e. genetic and/or epigenetic) factors in carcinogenesis by GTN.

9.4.4.4 Human Exposure Incidents and Epidemiological Studies

In a workplace environment, GTN is toxic by inhalation and absorption through skin. Several occupational exposure studies showed that skin resorption is a more likely pathway for intoxication than inhalation. It is very important to use proper gloves and replace them frequently. GTN causes severe headaches in exposed workers and a lowering of blood pressure.

Plasma GTN concentrations were studied in 12 volunteers in a gunpowder factory [446]. Serial blood samples were obtained from the cubital vein before and during work at two sites of production. High concentrations of GTN were detected in most plasma. Control specimens from a femoral vein contained much less GTN, indicat-

ing that blood in the cubital vein was enriched by dermally absorbed GTN. In the roll mill area concentrations of GTN in the cubital vein were higher than in the press area, but individual factors were also important since some workers consistently had higher concentration of GTN than others. Differences in absorption were more important than differences in the metabolism of GTN since only a small variation in disappearance rate was found after a controlled sublingual test dose of GTN given in a location away from the workplace. The major discomfort experienced was a headache that increased during working hours, but this was not significantly related to GTN concentrations in the air or in the blood from the cubital vein. The observations implied that major efforts should be made to reduce dermal contact with GTN during propellant production work.

Like the effects of EGDN in lowering the blood pressure, the body eventually develops a greater tolerance to GTN with prolonged exposure, but that does not mean that prolonged exposure is safe. An excess mortality from chronic cardio-cerebrovascular diseases among dynamite workers has been reported from the explosives industry [306]. The exposure situation with regard to EGDN and GTN during two decades in one of these factories has been correlated to epidemiological statistical evaluation data of worker medical histories. The mean 8-h TWA concentrations of nitrate esters for different job types were retroactively calculated from a large number of semiannually measured short-time samples. See also [447, 448].

9.4.4.5 Government Regulations for Maximum Allowable Glycerol Trinitrate Vapor Concentrations

The following vapor exposure limits for GTN were established by various agencies:

- ACGIH: 0.05 ppm (skin) (1994)
- NIOSH: STEL 0.1 mg/m³ (skin)
- NIOSH REL: ST 0.1 mg/m³ (skin)
- OSHA: Ceiling 0.2 ppm (skin)
- OSHA PEL: Ceiling 0.2 ppm (2 mg/m³) (skin)
- OSHA PEL-CL: 0.02 ppm (skin), TLV TWA: 0.05 ppm or 0.5 mg/m³ (skin)
- OSHA TLV-STEL: 0.1 ppm or 1.0 mg/m³ (skin).

For conversions from one unit to another, it is helpful to have the conversion factor 1 ppm = 9.29 mg/m³ @ NTP.

Based on the carcinogenicity of GTN observed in animal tests with rats, German health authorities in 2005 categorized GTN as a Category 3B carcinogen and suspended the TLV TWA of 0.005 mL/m³ that had been in effect since 1995 [449, 450]. The BEI values of 0.5 µg/L 1,2-GDN and 1,3-GDN in blood plasma were also repealed.

A very thorough summary of observed health problems in workers in dynamite and gunpowder factories is contained in the criteria document that NIOSH used to arrive at a recommended maximum allowable concentration of GTN (and EGDN) in workroom air [451].

The original NIOSH IDLH of 500 ppm was lowered by almost one order of magnitude to 75 ppm after a review of the literature and after additional data became available [452, 453]. Where data for GTN were lacking, quite often a comparison with EGDN was made to arrive at presumably safe levels of emergency exposure.

9.4.4.6 Biological Exposure Indices for Glycerol Trinitrate

Traditional practices with respect to the use of protective gloves at US Army ammunition plants that manufacture and incorporate GTN were critically reviewed, and the availability of alternate and presumably superior types of gloves was examined [454]. A literature review with respect to exposure indices suggested that it may be possible to monitor GTN exposure with GTN and/or its metabolites in plasma and urine, but that further research would be necessary before any of these control options could be routinely used. Urinary NG metabolites represented the best prospect for BEI monitoring since urine is easier to collect than plasma and is not complicated by factors such as the site of collection, which must be considered for blood. Before urine could be used for routine BEI monitoring, additional human studies of the characteristics of metabolites and the time course of their appearance/disappearance in urine during dermal exposure under controlled conditions would be necessary.

BEI monitoring to assess worker exposure workers to GTN has been difficult due to the short half-life of NG and its metabolites. A method to assess NG and its metabolites (GDNs) in urine would make biological monitoring more feasible. Samples taken from three sites using GTN, two munitions manufacturing sites and a pharmaceutical manufacturing site, were analyzed, and the samples taken at the two munitions sites contained 0.9–18 and 0–4.7 $\mu\text{mol/mol}$ creatinine, respectively, and the one at the pharmaceutical site contained 0–0.9 $\mu\text{mol/mol}$ creatinine [455]. The presence of glycerol di- and mononitrates in the urine of workers despite the use of personal protective equipment and local exhaust ventilation showed the usefulness of biological monitoring to assess the efficacy of any controls already in place and the continued potential of dermal absorption of NG.

The effects of inhaled or percutaneously administered NG on coronary flow in the coronary artery, left ventricular pressure, and ECG in dogs was measured by Doppler flow probes and implantable pressure transducers [456, 457]. It was shown that dogs exposed to NG by inhalation suffered pressure drop symptoms slightly, but that dogs treated percutaneously with 1.0 g NG daily did not show symptoms. The percutaneous treatment produced marginal changes in pressure and flow, slowing of the heart rate, and a progressive deterioration of the ECG patterns. Studies on uptake of tritiated NG confirmed that NG was absorbed through the skin, but later it could not be detected in the blood.

9.4.5 Safety and Hazard Properties of Glycerol Trinitrate

There have been numerous explosion accidents in the manufacture, transportation, and usage of GTN [458]. The strand burning of liquid GTN will be discussed in *Encyclopedia of Monopropellants*.

9.4.5.1 Drop Weight Impact Sensitivity of Glycerol Trinitrate

The drop weight impact sensitivity of GTN in the BAM tester is $0.02 \text{ kg m} = 0.2 \text{ N m}$ [74].

The impact sensitivity of liquid NG (50% point) was observed to be near 1.8 kg-cm or $3.3 \times 10^3 \text{ J/m}^2$ [459]. The impact sensitivity of solid NG (50% initiation level) was observed by extrapolation to be near 200 kg-cm or $4.4 \times 10^5 \text{ J/m}^2$. The impact sensitivity of a mixture of solid and liquid GTN was comparable to solid GTN at the two stimulus levels tested. Thus, the presence of solid GTN reduces the impact sensitivity of liquid GTN. See also [263, 460].

9.4.5.2 Shock Sensitivity of Glycerol Trinitrate Mixtures

The shock sensitivity of GTN and other liquid explosives depends on the shock pressure and the sonic velocity of the medium [461]. It may also depend on the amount of gas saturation and bubbles release of the liquid.

9.4.5.3 Card Gap Sensitivity of Glycerol Trinitrate Mixtures

Low-velocity reactions can often be observed in containers of high sound velocity such as glass, iron, and aluminum ($5000\text{--}6000 \text{ m/s}$) but not in containers of low sound velocity, like lead and Lucite (1200 and 2500 m/s , respectively). Copper was observed to be intermediate in sound velocity (3500 m/s). The container material affects the results of detonability testing.

While both GTN and EGDN by themselves are used as plasticizing agents for double-base propellants, it was hoped that mixtures of the two nitrates would be less sensitive and less prone to accidental explosions during processing of double-base propellants. Studies were conducted at 298 K (25°C) with a 50–50 mixture of GTN and EGDN (GTN-EGDN) in approximately 1-in.-ID $\times$ 16-in. L steel or aluminum containers of varying wall thicknesses [462]. The card gap was plotted as a function of wall thickness of the containment vessel. For 50-50 GTN-EGDN the gap versus wall thickness relationship for high-velocity detonation (approximately 7500 m/s) was found to have a negative slope in both steel and aluminum containers, as with other liquid explosives. Low-velocity reactions (approximately 2000 m/s or less) were obtained with NG-EGDN in 0.51-, 0.89-, and 3.4-mm (0.020-, 0.035-, and 0.133-in.) wall thicknesses at gaps up to and including 30.5 cm (12 in.), and data points were scattered all over the graph. The detonation velocity with zero gap was 7550 m/s .

9.4.5.4 Friction Sensitivity of Glycerol Trinitrate

Testing the friction sensitivity of GTN in the BAM friction sensitivity test apparatus was somewhat surprising in that no reaction was observed at the maximum load of the machine with a pistil load of 353 N [74].

9.4.6 Disposal of Glycerol Trinitrate

The epoxides glycidol and GLYN are formed during chemical desensitization of GTN-containing waste streams with calcium hydroxide [463]. The epoxide rings of both

compounds are unstable to heat in aqueous solutions and the rings open up to form glycerol 1-mononitrate and some glycerol. These transformations are accelerated by microbiological activity. Glycerol 1-mononitrate is slowly denitrated to form glycerol. Glycidol and GLYN caused base pair substitutions in the Ames test for mutagenicity while glycerol 1-mononitrate tested negative.

The safe disposal of spent acid from the manufacture of GTN is a major environmental challenge. It is not sufficient to simply dilute and neutralize the spent acid before releasing it to surface water since it contains some GTN that was dragged over from the separator.

9.4.7 Biodegradation of Glycerol Trinitrate

GTN spilled on the ground or leached from abandoned propellants and soaking into the soil will deteriorate naturally by bacterial action. GTN is biotransformed through a series of successive denitration steps, including GDN and GMN isomers, with each successive step slower than the previous step [395, 396, 464]. Glycerol is mineralized by biological systems. Glycidol and glycidol nitrate, formed by the chemical desensitization of GTN, are also mineralized. The biotransformation pathway of these compounds proceeds from GLYN to 1-mononitrate to glycerol, with slower rates at each succeeding step.

One method to reduce environmental pollution from GTN in wastewater from explosives and propellant factories would be to treat the water in holding ponds with active bacteria cultures capable of reducing GTN and hydrolysis products.

Bacteria capable of metabolizing GTN were isolated under aerobic and nitrogen-limiting conditions from soil, river water, and activated municipal sewage sludge [465]. One of these strains, from sewage sludge, chosen for further study was identified as *Agrobacterium radiobacter* subgroup B. A combination of HPLC and NMR analyses of the culture medium during the growth of *A. radiobacter* on basal salts-glycerol-GTN medium showed the sequential conversion of GTN to GDNs and GMNs. Isomeric glycerol 1,2-dinitrate and glycerol 1,3-dinitrate were produced simultaneously and concomitantly with the disappearance of GTN, with significant regioselectivity for the production of the 1,3-dinitrate. Dinitrates were further degraded to glycerol 1- and 2-mononitrates, but mononitrates were not biodegraded. Extracts of broth-grown cells contained an enzyme which in the presence of added NADH converted GTN stoichiometrically to nitrite and a mixture of GDNs. The specific activity of this enzyme was increased 160-fold by growth on GTN as the sole source of nitrogen.

Four axenic bacterial species capable of biodegrading GTN were isolated from soil samples taken from a wash water soakaway at a disused GTN manufacturing plant [466]. The isolates were identified by 16S rRNA gene sequence homology as *Pseudomonas putida*, an *Arthrobacter* species, a *Klebsiella* species, and a *Rhodococcus* species. Each of the isolates utilized GTN as its sole nitrogen source and removed

nitro groups sequentially from GTN to produce GDNs and mononitrates (GMN), with the exception of the *Arthrobacter* strain, which achieved removal of only the first nitro group within the time course of the experiment. The *Klebsiella* strain exhibited a distinct preference for the removal of the central nitro group from GTN, while the other five strains exhibited no such regioselectivity. All strains that removed a second nitro group from glycerol 1,2-dinitrate showed regiospecific removal of the end nitro group, thereby producing glycerol 2-mononitrate. Most significant was the finding that the *Rhodococcus* species was capable of removing the final nitro group from GMN and thus achieved complete biodegradation of GTN. Such complete denitration of GTN was previously shown only in mixed bacterial populations and in cultures of *Penicillium corylophilum* supplemented with an additional carbon and nitrogen source. This was the first report of a microorganism that can achieve complete denitration of GTN.

During a study of the reactions of the old yellow enzyme and reduced flavins with organic nitrate esters, it was found that reduced flavins reacted readily with GTN and PGDN, with rate constants at pH 7.0, 298 K = 25 °C of 145 and 5.8 mol⁻¹ s⁻¹, respectively [467]. With GTN, the secondary nitrate was removed reductively six times faster than the primary nitrate, with liberation of nitrite. With PGDN, on the other hand, the primary nitrate residue was three times more reactive than the secondary residue. In the old yellow enzyme-catalyzed NADPH-dependent reduction of GTN and PGDN, rapid-reaction studies of mixing reduced enzyme with the nitrate esters showed that a reduced enzyme-substrate complex is formed before oxidation of the reduced flavin. The rate constants for these reactions and the apparent K_d values of the enzyme-substrate complexes revealed that the rate-limiting step in catalysis is a reduction of the enzyme by NADPH. Reduction of the primary nitrate in both GTN and PGDN was favored by comparison with the free-flavin reactions. See also [468, 469].

9.4.8 Transportation of Glycerol Trinitrate

In pure form, GTN is too sensitive and unstable for indefinite storage or transport and must be quickly used as soon as it is received or produced. GTN is not usually transported but used immediately at the location of its production. Transportation of GTN makes for a good plot element in thrillers such as *The Wages of Fear* (*Le Salaire de la peur*, 1953 [470]), one of the author's favorite movies. The consequences of explosion of a truckload of GTN destined for snuffing out a burning oil well were graphically illustrated.

For shipment, GTN must be desensitized with not less than 40% of a non-volatile, water-insoluble phlegmatizer per UN 0143.

9.4.9 Explosive Performance of Glycerol Trinitrate

The detonation velocity of GTN at a density of 1.59 g/cm³ is 7750 m/s. Detonations in GTN can propagate by LVD [328].

9.5 Glycerol Dinitrate

The two glycerol dinitrates, also known as GDN, dinitroglycerin, glycerol dinitrate, $C_3H_6N_2O_7$, isomers may be found as contaminants in GTN due to incomplete nitration or premature hydrolysis or partial biodegradation and digestion. GDN is also made deliberately as a less-sensitive additive to propellant formulations. It is the raw product from which GLYN can be made by dehydration, which is then used to make polyGLYN, an energetic binder. 1,2-GDN is prepared by the nitration of glycerol with nitric acid, but such nitrations mostly yield mixtures of di- and trinitroglycerin. 1,2-GDN is a product of GTN metabolism where GTN was used as a medication to lower blood pressure. The metabolic products are 1,2-GDN, CAS RN [621-65-8], 1,3-GDN, CAS RN [623-87-0], and 1-GMN, CAS RN [624-43-1].

9.5.1 Physical Properties of Glycerol Dinitrate

The molecular mass of GDN is 182.1 g/mol. GDN is a viscous liquid that freezes at 243 K ($-30^\circ\text{C} = -22^\circ\text{F}$). The density of the liquid at room temperature is 1.51 g/cm^3 .

9.5.2 Chemical Properties of Glycerol Dinitrate

GDN is a viscous liquid but is more volatile and more soluble in water than GTN. It is hygroscopic and may be used as a gelatinizer of certain types of nitrocellulose in the preparation of double-base propellants. It is thermally more stable than GTN. Its vapors are just as toxic as GTN's and cause headaches.

While GTN is oxygen rich, its less nitrated precursor GDN is underoxidized and the oxygen balance is -17.58% for combustion to CO_2 .

9.5.2.1 Analysis of Glycerol Dinitrate

The historically used methods for the determination of GTN in cordite are not specific for that particular ester of nitric acid; the reagents will act in the same way on every organic nitrate, including the dinitrate of diethylene glycol. The isolation of the free polyvalent alcohol by reductive hydrolysis with alkali sulfite and their identification through crystalline derivatives are tedious and would lead to complications when mixtures of two nitrates are present. A comparison of IR spectra of NG and DEGDN showed that while either will exhibit the same absorption bands characteristic of the C—O—NO_2 group, only in the latter is the ether group C—O—C present. The ether group has a specific absorption at about 1130 cm^{-1} . Analysis of the spectra showed that both substances have a common IR absorption band between 1270 and 1280 cm^{-1} [NG 1273 cm^{-1} ($7.68\mu\text{m}$), DEGDN 1278 cm^{-1} ($7.3\mu\text{m}$)], and that only DEGDN shows an additional peak at 1140 cm^{-1} ($8.77\mu\text{m}$). This absorption band can, therefore, serve to indicate the presence of DEGDN in propellant mixtures that contain both NG and DEGDN [471].

9.5.3 Explosive Properties of Glycerol Dinitrate

The drop weight impact sensitivity in the BAM machine is 1.5 Nm, less sensitive than GTN, which has a 50% chance of ignition at a stimulus of only 0.2 Nm. If initiated to explosion in the lead block test, the resulting cavity volume is 450 cm³/10 g. Other sources give the lead block indentation as 500 cm³, which is 82% of that of GTN.

10 C₄ Alkyl Polynitrates

10.1 1,3-Butanediol Dinitrate

1,3-Butanediol dinitrate, also known as 1,3-butylene glycol dinitrate, C₄H₈N₂O₆, BDN, BDDN, CAS RN [6423-44-5], is a colorless oily liquid, with a density of 1.32 g/cm³, insoluble in water, but soluble in most solvents that are also used for GTN. It is more volatile than GTN. Nitrocellulose is readily gelatinized. The nitrate is very easily destroyed by oxidation, and sometimes the reaction mixture during its attempted synthesis decomposed generating heat and nitrous gases. The product cannot be obtained under industrial conditions and for this reason has not found any practical applications.

1,3-Butanediol dinitrate is a powerful explosive with a lead block cavity enlargement of 370 cm³/10 g. The flame reactions of the two isomeric dinitrates of butanediol have been investigated [472].

The structural isomer 1,4-butanediol dinitrate, CAS RN [3457-91-8], could not be made to explode when tested for impact sensitivity in comparison to GTN and other energetic liquids [263].

10.2 1,2,4-Butanetriol Trinitrate

The most common C₄ energetic plasticizer is 1,2,4-butanetriol trinitrate (BTTN), butane-1,2,4-triyl trinitrate, C₄H₇N₃O₉, BTTN, CAS RN [6659-60-5], *M* = 241.1131. BTTN is essentially a GTN with an extra methylene group inserted between two of the carbons that bear nitroxy groups:

The additional methyl group makes the molecule less reactive than GTN. BTTN is a pale yellow oily liquid with a density of 1.52 g/cm³ and a solidification point of 246 K = -27 °C = -17 °F. It has a lower vapor pressure than GTN and was sometimes used in double-base propellants intended for operation in tropical climates where NG might have bled (=exuded) out of the propellant grains during storage.

Less frequently used isomers of 1,2,4-butanetriol trinitrate are 1,2,3-butanetriol 1,2,3-trinitrate, α-methylglycerol trinitrate, O₂NOCH₂CH(ONO₂)CH(ONO₂)CH₃, CAS RN [84002-64-2], with a density of 1.489 g/cm³ at 293 K (20 °C) and 1,3-propanediol,

2-[(nitrooxy)methyl] dinitrate = trimethylolmethane trinitrate $\text{O}_2\text{NOCH}_2\text{CH}(\text{CH}_2\text{ONO}_2)=\text{CH}_2\text{ONO}_2 = \text{CH}(\text{CH}_2\text{ONO}_2)_3$, CAS RN [82975-75-5].

10.2.1 Physical Properties of 1,2,4-Butanetriol Trinitrate

The physical properties of BTTN are summarized in Table 56. See also [473, 474].

Table 56: Physical properties of 1,2,4-butanetriol trinitrate.

Property	SI units	Other units	References
Molecular mass	241.1131	241.1131	[73]
Freezing point	246 K	$-27^\circ\text{C} = -17^\circ\text{F}$	Manufacturer's data sheet
Melting point	267.2 K	-5.9°C	[407]
Boiling point	503 K	446 °F	Manufacturer's data sheet
Density at 293 K	1.52 g/cm ³		Manufacturer's data sheet
Vapor pressure	0.147 Pa @ 293 K	0.0011 mm Hg at 20 °C	Manufacturer's data sheet
Viscosity at 293 K	0.059 N s m ⁻²	59 cPs	Manufacturer's data sheet

Heat of formation		-386 cal/g	[377]
Heat of formation	-374.5 kJ/mol	$-371.2 \text{ kcal/kg} =$ -89.5 kcal/mol	[74]
Heat of formation	-414 kJ/mol	-98.9 kcal/mol	[302]
Heat of combustion, solid	2176 kJ/mol	520.2 kcal/mol	[302]
Heat of combustion, liquid	2311 kJ/mol	552.3 kcal/mol	[302]

Most previously published data on freezing points of nitrate esters were obtained by freezing point measurements instead of melting point measurements. These data tend to be low because of the strong tendency for nitrate esters to supercool and also because of low-melting-point, metastable, allotropic crystal formation by the pure materials. The melting points of stable-form, nitrate ester crystals were measured by DSC and confirmed by visual observations [407]. These data were already shown in Table 51 in the GTN section of this book. Similar data were obtained on GTN/BTTN and TMETN/BTTN mixtures.

Many alkyl nitrates and polynitrates have a tendency to supercool and don't crystallize voluntarily. Therefore, it is difficult to determine a freezing point by cooling a liquid sample. A systematic study was conducted of four nitrate esters, GTN, BTTN, TMETN, and TEGDN, which are used to better control the crystallization phenomena of plasticizers in propellants [406]. The tests were conducted to determine the melting characteristics of these four frozen compounds and to compare new measurements to the old data in the literature, which were sometimes incomplete or unreliable. The influence of temperature on the rate of crystal growth was studied for four nitric esters by visual observation, and nucleation was specifically considered for GTN and

TMETN, the two nitrate esters that exist in allotropic modifications and may form two crystallographic different varieties, depending on the mode of nitration and the temperature/time history. The melting point of frozen BTTN was 263 K (−10 °C), and the heat of fusion was 15.1 kJ/mol = 63 J/g = 3.62 kcal/mol = 15 cal/g.

10.2.2 Chemical Properties of 1,2,4-Butanetriol Trinitrate

10.2.2.1 Thermal Stability of 1,2,4-Butanetriol Trinitrate

The steady-state combustion of BTTN has been modeled using a one-dimensional model and detailed kinetics [475, 476]. A global decomposition reaction for the condensed phase has been postulated based on experimental data and the evaporation of BTTN was included in the model. A detailed gas-phase kinetic mechanism consisting of 534 reactions and 83 species has been used. The combustion has been modeled over a pressure range of 5–100 atm and initial temperatures of 298 ± 50 K. The calculated combustion characteristics included the burning rate, pressure exponent, temperature sensitivity, surface and flame temperatures, temperature and species profiles, and condensed- and gas-phase heat release. The calculated values were compared to the available experimental data on BTTN and other similar nitrate esters. The strand burning rates of BTTN and BTTN mixtures will be discussed in *Encyclopedia of Monopropellants*.

There are three different locations of the —ONO₂ groups in the molecular structure of BTTN: α-O—NO₂, β-O—NO₂, and δ-O—NO₂. The cleavage of each of the three O—NO₂ bonds must be considered when building a model of the decomposition of BTTN. In addition to the dissociation of the O—NO₂ bond, there will be a competitive HONO elimination one NO₂ group from BTTN. Therefore, six possible competitive initial decomposition pathways of BTTN must be considered. Homolysis of one of the O—NO₂ bonds occurs to form •NO₂ and CH₂ONO₂CHONO₂CH₂CH₂O•, which subsequently decomposes to form CH₃CHO + •CHO + 3NO₂ + HCHO. In the second, successive HONO elimination reactions yield three HONO and OHCCH₂CHONO₂CH₂ONO₂ fragments, which subsequently decompose to form CH₃CHO + 2CO + 3HONO. The first pathway has a slightly lower activation energy than the second. The results showed that the pathway involving O—NO₂ cleavage is slightly more energetically favorable than that involving HONO elimination. Computations gave the BDEs required for the departures of α-NO₂, β-NO₂, and δ-NO₂ as 139.81, 140.46, and 132.15 J/mol, respectively [477]. Thus, it became apparent that the homolytic cleavage of δ-O—NO₂ would be preferred in the decomposition of BTTN. For HNO elimination, the activation energies of the three possible elimination pathways were 156.65, 153.77, and 149.37 J/mol, respectively. Again, this showed that the cleavage of δ-O—NO₂ is preferred in the decomposition of BTTN.

10.2.2.2 Reactions of 1,2,4-Butanetriol Trinitrate

The supermolecular systems of BTTN with polyethylene glycol (PEG), HTPB, glycidyl azide polymer (GAP), poly(3-azidomethyl)-3-methyl-oxetane (AMMO), and poly(3,3-bis(azidomethyl)-oxetane) (BAMO) were calculated by semiempirical molecular orbital theory methods [478]. The binding energies of the optimized geometrical structures were obtained with dispersion energies being corrected. The binding energies (absolute values) of BTTN with HTPB and AMMO increased as the molecular chain of polymers increased. However, there was a deviation from the preceding rule on the binding energies of BTTN with BAMO, GAP, and PEG with increases in the molecular chain. The binding energies of BTTN with GAP, AMMO, and BAMO were slightly larger than those of BTTN with the other two polymer binders (PEG and HTPB).

10.2.2.3 Analysis of 1,2,4-Butanetriol Trinitrate

Impurities in the raw material 1,2,4-butanetriol and in the finished product 1,2,4-BTTN can be analyzed by ion chromatography (IC), HPLC, NMR, capillary GC, and GC/MS [479].

A GC method for the separation and quantitative determination of glycerol and 1,2,4-butanetriol conitration products by a method using external standard calibration achieved a relative standard deviation of less than 1% [480, 481].

10.2.3 Handling of 1,2,4-Butanetriol Trinitrate

BTTN must be diluted to a maximum of 80% BTTN with methylene chloride for shipment. It can be shipped under a limited-time exemption permit as a Class A, Type 8 high explosive liquid (Federal Register 59, #249:67395, Dec. 29, 1994). A stabilizer is not required, but 2-NDPA or ethyl centralite can be added prior to shipment on special request.

10.2.4 Toxicity of 1,2,4-Butanetriol Trinitrate

In parallel tests with 1,2,4-butanetriol 1,2,4-trinitrate by oral gavage to rats, the LD50 was 1587 mg/kg in one test and 1027 mg/kg in another test.

10.2.5 Explosive Properties of 1,2,4-Butanetriol Trinitrate

The drop weight impact sensitivity of BTTN as determined in the Bureau of Mines apparatus with a 2-kg mass was 58 cm. In the Picatinny Arsenal apparatus, the sensitivity was 25 mm (1 in.) with a 2-kg mass. In a ballistic mortar, the performance of BTTN was 137% of that of TNT.

10.3 Diethylene Glycol Dinitrate

Diethylene glycol dinitrate, also known as DEGDN, C₄H₈N₂O₇; ethanol, 2,2'-oxybis-, dinitrate; diglycol dinitrate, CAS RN [693-21-0], is a highly energetic material that can be used either as an explosive by itself or, most often, as an energetic plasticizer in double-base solid propellants. It is slightly underoxidized with an oxygen balance of -40.8%:

DEGDN was used extensively in WWII by the German side as one of the main components of double-base propellants [482]. Fedoroff, *Encyclopedia of Explosives and Related Items*, Vol. 5, contains only relatively little information on DEGDN on pages D1232-D1233.

One book on liquid explosives contains illustrations of equipment used for production of DEGDN [39].

10.3.1 Physical Properties of Diethylene Glycol Dinitrate

The physical properties of DEGDN are summarized in Table 57. See also [483, 484].

Table 57: Physical properties of DEGDN.

Property	SI units	Other units	References

Data source: [15]

The solubility of DEGDN in water is 0.40 g/100 g water at 298 K. The IR spectrum of DEGDN is shown in Figure 31.

Figure 31: IR spectrum of DEGDN. (From [296].)

The IR spectra of DEGDN and six other dinitrate esters were computed by a DFT method [297].

A Raman spectrum of DEGDN in comparison to the spectra of TMETN and PGDN was shown in [26].

10.3.1.1 Thermodynamic Properties of Diethylene Glycol Dinitrate

The thermodynamic properties of DEGDN are summarized in Table 59.

Table 59: Thermodynamic properties of DEGDN.

Property	SI units		Other units		References
Enthalpy of formation at 298 K, liquid	-433 kJ/mol	-2208 kJ/kg	-103.5 kcal/mol	-528 kcal/kg	[74]
Enthalpy of formation at 298 K, liquid	-451.0 kJ/mol	-2300 kJ/kg	-107.8 kcal/mol	-550 cal/g	[73]
Enthalpy of formation at 298 K, liquid	-426.7 kJ/mol	-2176 kJ/kg	-102.0 kcal/mol	-520 cal/g	[377]

Heat of fusion at 276.5 K	25.4 kJ/mol		6.07 kcal/mol	30.9 kcal/kg	[73]

The heat capacities of liquid, glassy, and crystalline DEGDN were measured in a vacuum adiabatic calorimeter in the range 80–320 K [485]. Two crystal modifications were identified, and their melting points and enthalpies were determined. The $H_0(T) - H_0(0)$, $S_0(T)$, and $G_0(T) - H_0(0)$ thermodynamic functions of crystalline and liquid DEGDN were calculated in the range 0–320 K.

10.3.1.2 Magnetic Properties of Diethylene Glycol Dinitrate

A complete analysis of the ¹H NMR spectra of 21 nitrate esters including DEGDN and GTN was not possible [27]. A small number, like the corresponding fluorides, gave deceptively simple spectra. In others the resolution was not sufficient to allow all the NMR parameters to be evaluated. It would be difficult to use NMR in the analysis of nitrate ester mixtures.

10.3.1.3 Molecular Structure of Diethylene Glycol Dinitrate

A DFT method was used to study the geometric and electronic structures and pyrolysis mechanisms of six dinitrate esters including DEGDN (DEGDN), TEGDN, Tetra-EGDN, pentaethylene glycol dinitrate (Penta-EGDN), and hexaethylene glycol dinitrate (Hexa-EGDN) [297]. The IR spectra of these compounds were obtained and the bands were assigned by vibrational analysis. Based on the principle of statistic thermodynamics, the thermodynamic properties were evaluated, which were linearly related to the number of repetitive $\text{CH}_2\text{CH}_2\text{O}$ groups as well as the temperature, showing good group additivity. The thermal stability and the pyrolysis mechanism of the dinitrate esters were investigated by calculating the BDEs. For the nitrate esters, the $\text{O}-\text{NO}_2$ bond is a trigger bond during a thermolysis initiation process. In the series $\text{O}_2\text{NO}-[\text{CH}_2\text{CH}_2\text{O}]_n\text{CH}_2\text{CH}_2\text{ONO}_2$, the enthalpy of formation ΔH_m increases on an average by 10.45 kJ/mol for each $\text{CH}_2\text{CH}_2\text{O}$ group that is added, which showed good group additivity of thermodynamic functions.

The interactions between nitrate plasticizer ingredients GTN, DEGDN, and TEGDN were investigated theoretically and experimentally [486]. DFT and second-order perturbation theory (MP2) calculations showed that intermolecular $\text{N}-\text{O}$ electrostatic interactions and hydrogen bonding between alkyl hydrogens and oxygen atoms govern the dimer structures, which predicted binding energies ranging from 20.6 to 39.3 kJ/mol. Vibrational frequencies observed in the nitrate band fingerprint region of the IR spectra were in good agreement with the DFT scaled harmonic frequencies. The relative volatility observed in thermogravimetric analysis (TGA) measurements of the pure ingredients, and their 1:1 mixtures showed reasonable correlation with the DFT dimer binding energies. The similarity in the dimer binding energies of all three plasticizers suggested that their mixtures should be uniformly miscible.

10.3.2 Chemical Properties of Diethylene Glycol Dinitrate

DEGDN is miscible at ordinary temperatures with GTN, EGDN, ether, acetone, methanol, chloroform, and benzene. It is not miscible with ethanol and is sparingly soluble in carbon tetrachloride. It has a low hygroscopicity and is sparingly soluble in water but more soluble in water than GTN. Its vapors produce headaches, though not as strong as those produced by EGDN vapors.

10.3.2.1 Decomposition of Diethylene Glycol Dinitrate

The thermal stability and thermal decomposition properties of four alkyl nitrates, including DEGDN and TEGDN, was examined by ARC under adiabatic conditions [185]. The onset temperature, the initial temperature rise rate and the maximum temperature rise rate were recorded. The apparent activation energy and preexponential factors of the thermal decomposition were calculated. The self-accelerating decomposition temperatures (SADT) of four nitrates in three different containers (4.5-L iron drum, 25-L iron drum, and 210-L fiber drum) were calculated. It was concluded that the on-

set temperatures of TEGDN and DEGDN were 423.7 and 423.7 K (both 150.6 °C), respectively, while the maximum temperature rise rates of TEGDN and DEGDN were 59.7 and 209.8 °C/min, with the apparent activation energy of TEGDN and DEGDN being 226.4 and 214.5 kJ/mol. The thermal stability of the four nitrates was ranked (from worst to best): DEGDN TEGDN NPN IPN.

10.3.3 Safety Properties of Diethylene Glycol Dinitrate

10.3.3.1 Toxicity of Diethylene Glycol Dinitrate

As of 1983, the completeness of health and toxicity information on three widely used energetic plasticizers (DEGDN, TEGDN, and TMETN) left some to be desired, and the need for additional research was outlined [487].

10.3.3.1.1 Oral Toxicity of Diethylene Glycol Dinitrate

The acute oral toxicity of DEGDN was determined in rats by the oral gavage single-dose method [488]. The LD₅₀ was 990.4 ± 30.0 mg/kg for male rats and 753.1 ± 35.9 mg/kg for female rats. Similar tests in mice indicated an LD₅₀ of 1395 ± 59 mg/kg for male mice and 1321 ± 74 mg/kg for female mice [489]. Clinical signs produced by DEGDN intoxication included twitching, tremors, hypertonia, squinting, lacrimation, depression of grasping and righting reflexes, jumping, increased startle reflex, ataxia, cyanosis, and prostration. The extent of the neurotoxic component of these clinical signs suggested that DEGDN possesses additional pharmacological properties in addition to those routinely associated with other nitrate esters. Most animals were exhibiting signs within 2 h after dosing and had either perished or cleared by 72 h after dosing.

10.3.3.1.2 Dermal Toxicity of Diethylene Glycol Dinitrate

The acute dermal toxicity of DEGDN was evaluated in rabbits by applying DEGDN topically to the clipped dorsal skin surface under a semioclusive wrap for 24 h [490]. A limit dose of 2 g/kg did not produce deaths or clinical (systemic or dermal) signs during the 2-week observation period that could be attributed to administration of DEGDN.

In a similar test, the primary dermal irritation potential of DEGDN was determined in rabbits using a modified Draize procedure with a 4-h application period [491] or in guinea pigs [492]. Neither edema nor erythema, or any other recognizable skin reaction, was detected at any time during the 72-h observation period. Similar tests were conducted for triethylene glycol dinitrate (Section 12.1.4.1).

The DEGDN eye irritation potential was evaluated in rabbits using a modified Draize method [493]. DEGDN produced no irritation upon direct contact with the eye. Slight iridial vasodilation and slight conjunctival vasodilation and swelling, indicative of mild inflammation, were the most serious responses observed. DEGDN was classified as a non-irritant under conditions of this study.

10.3.3.1.3 Mutagenicity of Diethylene Glycol Dinitrate

DEGDN was not mutagenic under conditions of the Ames *Salmonella*/mammalian microsome mutagenicity testis test with doses ranging from 5 to 0.0016 $\mu\text{L}/\text{plate}$ [494].

10.3.4 Explosive Properties of Diethylene Glycol Dinitrate

10.3.4.1 Impact Sensitivity of Diethylene Glycol Dinitrate

The drop weight impact sensitivity of DEGDN is 0.1 Nm, which is on the same order of magnitude as that of GTN. In the Picatinny apparatus with a 2-kg mass the impact sensitivity was 100 cm. DEGDN could be made to explode when tested for impact sensitivity in comparison to GTN and other energetic liquids [263].

10.3.4.2 Adiabatic Compression Sensitivity of Diethylene Glycol Dinitrate

In a U-tube adiabatic compression sensitivity test apparatus with variable, preselected push pressure, and constant bubble size, the push pressure required to explode DEGDN was higher than that of methyl nitrate or GTN, but similar to that of EGDN [111].

10.3.5 Explosive Performance of Diethylene Glycol Dinitrate

In the lead block test, explosion of 10 g DEGDN will widen the cavity to hold 410 cm^3 of water. The detonation velocity of unconfined DEGDN is 6600 m/s at a density of 1.38 g/cm^3 .

Mixtures of DEGDN with nitric acid exist during the nitration of diethylene glycol and may be more detonable than the product itself. The detonation of mixtures of concentrated (94–100%) nitric acid with DEGDN was studied, and the detonation failure diameter was measured in glass tubes [495]. The critical diameter of a stoichiometric mixture of nitric acid with DEGDN was 1 mm.

A DFT method was used to predict the explosive performance of six dinitrate esters including DEGDN, TEGDN, Tetra-EGDN, Penta-EGDN, and Hexa-EGDN [297]. Detonation performances were evaluated by the Kamlet-Jacobs equations based on the calculated densities and heats of formation. It was found that density, detonation velocity, and detonation pressure decreased with the increase in the number of $\text{CH}_2\text{CH}_2\text{O}$ groups. The predicted detonation velocity of DEGDN at a density of 1.59 g/cm^3 was 7.78 km/s, and the detonation pressure was 24.89 GPa, compared to 8.96 km/s and 35.03 GPa for EGDN.

10.4 Trimethylolmethane Trinitrate

Trimethylolmethane trinitrate, also known as 1,3-propanediol, 2-[(nitrooxy)methyl] dinitrate, 2-[(nitrooxy)methyl]propane-1,3-diyl dinitrate, $\text{C}_4\text{H}_7\text{N}_3\text{O}_9$, TMMTN, $\text{O}_2\text{NO}-\text{CH}_2\text{CH}(\text{CH}_2\text{ONO}_2)\text{CH}_2\text{ONO}_2 = \text{CH}(\text{CH}_2\text{ONO}_2)_3$, CAS RN [82975-75-5], has been syn-

thesized as an experimental chemical, but due to the limited availability of the parent polyol, TMMTN has not yet found widespread application as an energetic plasticizer. It is not to be confused with methyltrimethylolmethane trinitrate, which will be described subsequently in Section 11.1. TMMTN is an isomer of BTTN. Since a non-energy-contributing methyl group has been removed, the oxygen balance and energy content of TMMTN is improved over that of the homolog TMETN. All nitrate groups in TMMTN are connected to a primary carbon atom. The weak link in GTN is the nitrate group on the central, secondary carbon atom. TMMTN does not have such a nitrate group and thus should be thermally more stable than GTN:

The enthalpy of formation of TMMTN has not been determined experimentally, but because it is a structural isomer of 1,2,4-BTTN, it was assumed that the enthalpy of formation of TMMTN was identical to that of BTTN, which is $-397 \text{ kJ/mol} = -95 \text{ kcal/mol}$.

TMMTN is a clear liquid at room temperature with a density of 1.53 g/cm^3 . Only very pure samples can be induced to crystallize when the sample is cooled to $285\text{--}286 \text{ K}$ ($+12\text{--}13^\circ\text{C}$). It is insoluble in water but soluble in most organic solvents except tetrachloromethane. It is less volatile than TMETN, which in turn is less volatile than GTN. This is an advantage for its intended use as an energetic plasticizer in double-base propellants, where the migration of GTN has been a long-standing problem.

10.5 Nitroisobutylglycerol Trinitrate

Nitroisobutylglycerol trinitrate, also known as nitroisobutylglyceryl trinitrate, NIBGT, C₄H₆N₄O₁₁, nib-glycerin trinitrate, 2-nitro-2-nitroxymethyl-propane-1,3-diol dinitrate, nitroisobutanetrinitrate, NIBTN, CAS RN [20820-44-4], is a yellow viscous oil:

2-nitro-2-nitroxymethyl-propane-1,3-diol dinitrate

We were looking for the best place in this book to reference alkyl nitrates that also carry a nitro group in the alkyl group. Should they be listed under alkyl nitro compounds, or should they be listed under alkyl nitrates? Since the reactivity of these compounds is more determined by the more labile nitroxy group, we have listed them under alkyl nitrates. A few of these compounds were also discussed in the sections on aliphatic nitro compounds.

NIBGT can be prepared by the condensation of formaldehyde with NM, followed by nitration of the nitroisobutylglycerol product under the same conditions as GTN. If during the condensation with formaldehyde only one instead of two methoxy groups are attached, the product is 2-nitro-2-methyl-1,3-propanediol, which upon nitration gives 2-nitro-2-methyl-1,3-propanediol dinitrate. This is likely to accompany NIBGT as a contaminant. The nitration and stabilization procedures are very difficult because of incipient decomposition reactions and the difficulty of separating the aqueous and non-aqueous phases after washing with sodium carbonate or sodium sulfite to remove excess acid [496].

The physical properties of NIBGT are summarized in Table 60. See also [497].

NIBGT is less volatile than GTN, which is an advantage, but it is thermally less stable than GTN, which is a disadvantage. It is practically insoluble in water and petroleum ether, but soluble in alcohol, acetone, diethyl ether, benzene, or chloroform. It is a good gelatinizer of nitrocellulose for the preparation of double-base propellants. Its explosive strength is close to that of GTN.

NIBGT is one of the few energetic plasticizers that are stoichiometrically balanced with an oxygen balance of $\pm 0\%$. Adding NIBGT to a double-base propellant formulation will therefore not cause the overall oxygen balance to drop as it would when conventional plasticizers were in use.

The thermal stability of NIBGT was evaluated and compared to that of other nitrate esters [498]. The thermal stability of NIBGT was compared to that of other nitrate

esters in an effort to explain the relationship between molecular structure and thermal stability [56].

10.6 Nitromethylpropanediol Dinitrate

2-Nitro-2-methylpropane-1,3-diol dinitrate, also known as methylnitropropanediol dinitrate, C₄H₇N₃O₈, CAS RN [4055-94-1], can be prepared by the condensation of nitroethane with formaldehyde and subsequent nitration of nitromethylpropanediol:

2-Nitro-2-methylpropane-1,3-diol dinitrate

Nitromethylpropanediol dinitrate has an oxygen balance of -24.9% and a nitrogen content of 18.67 mass-% N. The physical properties of 2-nitro-2-methylpropane-1,3-diol dinitrate are summarized in Table 61.

Table 61: Physical properties of 2-nitro-2-methylpropane-1,3-diol dinitrate.

11 C₅ Alkylpolynitrates

11.1 Trimethylolethane Trinitrate

Trimethylolethane trinitrate, also known as C₅H₉N₃O₉, CH₃—C(CH₂—O—NO₂)₃, 2-methyl-3-nitrooxy-2-(nitrooxymethyl)propyl nitrate, methyltrimethylolmethane trinitrate, 2-methyl-2-[(nitroxy)methyl]1,3-propanediol dinitrate; 1,3-propanediol, 2-methyl-2-[(nitrooxy)methyl]-, dinitrate; nitropentaglycerin, 2-methyl-2-nitroxy-methyl-1,3-dinitroxyropane, METN, TMETN, metriol trinitrate, metriole trinitrate, 1,1,1-trimethylolethane trinitrate; 1,3-propanediol, 2-(hydroxymethyl)-2-methyl-, trinitrate; 1,3-propanediol, 2-methyl-2-[(nitrooxy)methyl]-1,3-dinitrate; 1,3-propanediol, 2-methyl-2-[(nitrooxy)methyl]-, dinitrate (ester); CAS RN [3032-55-1], is a nitrate ester that can be used as a substitute gelatinizer for GTN. TMETN is a structural isomer of 1,2,5-pentanetriol trinitrate (C₅H₉N₃O₉). TMETN can be made by nitration of the alkanetriol trimethylolethane [500]:

TMETN is a high explosive similar to GTN but more stable to heat. It is a clear oily liquid, colorless to light brown. TMETN is a solid at subzero temperature and is often used in combination with BTTN or DEGDN/TEGDN. It has the advantage of being relatively insensitive to impact and friction. TMETN has been synthesized by nitrating 1,1,1-trimethylolethane (metriol) at 263 K (10 °C) with mixed acid (45% HNO₃ and 55% H₂SO₄) in 93% yield. Metriol in turn is prepared by the condensation of propanal with formaldehyde in a manner similar to that employed in the synthesis of pentaerythritol. Because of its low vapor pressure, TMETN does not induce headaches as badly as other nitrate esters do. It can be used in some solid propellants and smokeless powders as a plasticizer and gelatinizer together with, or as an alternative to, TEGDN.

TMETN was first prepared and patented in Italy under the name *Metriolo*. Germany began producing it even before WWII after TMETN (in combination with TEGDN) showed its usefulness as an erosion and flash-reducing agent in smokeless tube weapon propellants, in particular in those intended for use in hot climates. TMETN is insoluble in water, but readily soluble in acetone or NM.

TMETN can be initiated by friction, impact, and electrostatic discharge. It can be used as a high-viscosity plasticizer-binder together with nitrocellulose, but its poor colloiding properties may require adding an inert plasticizer and an auxiliary, but unfortunately more volatile, solvent/colloiding agent.

11.1.1 Physical Properties of Trimethylolethane Trinitrate

The physical properties of TMETN are summarized in Table 62. See also [69, 278, 501].

Similarly to GTN, TMETN crystallizes in a stable and a metastable form, one melts at 273.6 K (+0.5 °C) and the other at 288 K (+15 °C) [406]. The heat of fusion of TMETN is 15.1 kJ/mol = 63 J/g = 3.62 kcal/mol = 15 cal/g, similar to that of BTTN. Freezing points listed in the literature are probably the result of substantial supercooling before the sample solidified.

The vapor pressure of TMETN as a function of temperature can be expressed by the following equation [503]:

$$\log p = A - B/T$$

in which p is the pressure in μmHg , T is the absolute temperature in kelvin, and A and B are constants: $A = 14.6237$ and $B = 4603.4$. Table 63 has the raw data of the measured vapor pressure of TMETN in comparison to data interpolated with the foregoing equation.

Table 62: Physical properties of TMETN.

The solubility of TMETN in water at 298 K is 0.01 g TMETN/100 g H₂O. TMETN is miscible with diethyl ether or acetone. It is completely miscible with acetone, diethyl ether, methanol, toluene, or xylene. The IR spectrum of TMETN is shown in Figure 32.

A Raman spectrum of TMETN was already shown earlier in Figure 2 in comparison to the spectra of EGDN and PGDN [26].

The physical properties of TMETN and its higher homolog, TMPTN, are compared in Table 64 (repeating some of the data already shown in an earlier table).

Table 63: Vapor pressure of TMETN.

11.1.2 Chemical Properties of Trimethylolethane Trinitrate

With an oxygen balance of -34.5% , TMETN detracts some of the available oxygen in double-base propellants, but due to its positive enthalpy of formation it improves the performance of the propellant.

11.1.2.1 Reactions of Trimethylolethane Trinitrate

11.1.2.1.1 Hydrolysis of Trimethylolethane Trinitrate

Hydrolysis with alkaline ethanol solutions is a safe method for the disposal of TMETN [505]. Instead of the expected triol, a cyclic 3-methyl-oxetane methanol was formed as the hydrolysis product.

11.1.2.2 Thermal Stability of Trimethylolethane Trinitrate

The thermal decomposition of TMETN was investigated by pressure DSC [506]. The results showed that, even though TMETN has a structure similar to that of GTN, TMETN has totally different thermal decomposition characteristics. At normal pressure, TMETN has an exothermic decomposition peak, while NG has an endothermic peak. Under pressure, TMETN has two exothermic peaks. The shape, temperature, and quantity of heat of the two peaks change with the increase of pressure. The kinetic parameters of TMETN were obtained, and TMETN's decomposition mechanism has also been analyzed.

The thermal stability of TMETN was compared to that of other nitrate esters in an effort to explain the relationship between molecular structure and thermal stability [56].

11.1.2.3 Analysis of Trimethylolethane Trinitrate

The purity of TMETN for propellant applications is controlled by MIL SPEC WS 12798, Weapon Specification WS 12798 Metriol Trinitrate.

11.1.3 Safety Properties of Trimethylolethane Trinitrate

11.1.3.1 Toxicity of Trimethylolethane Trinitrate

As of 1983, the completeness of health and toxicity information on three widely used energetic plasticizers (DEGDN, TEGDN, and TMETN) left something to be desired, and the need for additional research has been outlined [507].

11.1.3.1.1 Oral Toxicity of Trimethylolethane Trinitrate

The acute oral toxicity of TMETN suspended in corn oil was determined in male and female ICR mice using the oral gavage single-dose method with doses ranging from 562 to 1590 mg/kg [508]. The calculated median lethal dose LD₅₀ for male mice was 829.0 ± 42.5 mg/kg and for female mice it was 658.4 ± 32.7 mg/kg. The LD₁₀ in male mice was 643.3 ± 54.8 mg/kg. TMETN had a strong effect on the nervous system, as indicated by the incidence of convulsions, tremors, twitching, writhing, jumping, and catalepsy.

These signs were observed within 2 h of dosing and the majority had resolved within 72 h of dosing. Deaths were observed acutely, with 86% occurring within 4 h of dosing; no deaths were observed after 24 h. Similar tests in rats gave an LD₅₀ of 1587 ± 191 mg/kg for male rats and 1027 ± 64 mg/kg for female rats [509, 510]. Again, clinical signs observed following TMETN administration were inactivity, tremors, irritability, clonic convulsions, depression of grasping and righting reflexes, changes in the startle reflex, disorientation, and hunched posture. Most animals exhibited signs within 2 h of dosing and had either died or returned to normal by 72 h after dosing.

Other sources give the toxicity of TMETN as LD₅₀ (mice): 562 mg/kg, 655–828 mg/kg; LD₅₀ (rats): 1030–1519 mg/kg, 2390–3100 mg/kg (oral).

11.1.3.1.2 Dermal Toxicity of Trimethylolethane Trinitrate

While other nitrate esters can be resorbed through the skin by handling plasticized propellants without glove protection, TMETN had only a very slight potential of permeation when tested for 24-h applications in rabbits at a topical dose of up to 2 g/kg [511]. There was no evidence of percutaneous absorption of quantities sufficient to produce systematic toxicity or death. In topical application tests, there was no recognizable skin reaction (visible irritation) at any time during the 14-day observation period in exposed rabbits [512, 513]. Slight primary eye irritation is caused by TMETN in rabbits [514].

TMETN was evaluated for its potential to produce dermal sensitization in male guinea pigs or guinea pigs [515]. The Buehler test, which utilizes repeated closed patch inductions with the test compound, was used for this evaluation. No evidence of TMETN-induced sensitization was observed.

11.1.3.1.3 Mutagenicity of Trimethylolethane Trinitrate

TMETN showed no mutagenic activity in the Ames *Salmonella*/mammalian microsome mutagenicity test [516].

11.1.3.2 Explosive Sensitivity of Trimethylolethane Trinitrate

The explosion of TMETN can be initiated by friction, impact, or electrostatic discharge. Autodecomposition of TMETN begins at the deflagration point of 455 K = 182 °C = 360 °F. The open-cup flash point of TMETN is 299.8 K = 26.7 °C.

The impact sensitivity of TMETN when impacted in the Olin Technoproducts tester with a 2-kg mass is 47 cm. In the Bureau of Mines impact tester with a 2-kg mass it is 40 cm. In the BAM tester the drop weight sensitivity is 0.2 Nm. It can be detonated with a No. 6 blasting cap.

In the electrostatic discharge sensitivity test, TMETN was negative at 12.42 J [502].

11.1.4 Explosive Performance of Trimethylolethane Trinitrate

When detonated in a lead block test, the resulting cavity enlargement is $400 \text{ cm}^3/10 \text{ g}$. The fully developed detonation velocity is 7050 m/s . In the lead block test, the indentation with TMETN was $400 \text{ cm}^3/10 \text{ g}$, which is 139% of that of picric acid or 140% of that of TNT.

The shock initiation of TMETN was tested in comparison to GTN and ethyl nitrate [158]. The donor charges were 3.5-cm-diameter Composition B pellets, 10 to 12.5 cm in length; the interruptors were 6.5×8.0 -cm square glass plates of varying thicknesses S_1 (3.2–9.3 mm) and the receptor explosive was contained in 4- to 7.5-cm-diameter glass cylinders. The initial wave velocity and delay to detonation were measured with a streak camera and were 4470 – $4970 \text{ mm}/\mu\text{s}$; the delays were 0.6 – $0.7 \mu\text{s}$.

11.1.5 Applications of Trimethylolethane Trinitrate

TMETN can be used as an energetic plasticizer in insensitive solid propellants [517].

TMETN (MTN) is used as a plasticizer in PBXN-103 per MIL-E-82756(OS). The nominal MTN content is 23%.

11.2 1,2,5-Pentanetriol Trinitrate

1,2,5-Pentanetriol trinitrate, $\text{C}_5\text{H}_9\text{N}_3\text{O}_9$, CAS RN [98071-55-7], is an energetic plasticizer, but, owing to the nitroxy group on a secondary carbon atom, its thermal stability is inferior to some of the other alkyl polynitrates in this category:

The physical properties of 1,2,5-pentanetriol trinitrate are summarized in Table 65.

Table 65: Physical properties of 1,2,5-pentanetriol trinitrate.

Property	SI units		Other units	References

12 C₆ Alkylpolynitrates

12.1 Triethylene Glycol Dinitrate

Triethyleneglycol dinitrate, also known as TEGDN, Tri-EGDN, O₂NO—CH₂—CH₂—O—CH₂—CH₂—O—CH₂—CH₂—ONO₂, C₆H₁₂N₂O₈, triglycol dinitrate, triethyleneglycol dinitrate, nitrotriglycol, 2,2-bis(ethylenedioxy)diethyl nitrate; ethanol, 2,2'-[(1,2-ethanediyl)bis(oxy)]bis-1,1'-dinitrate; CAS RN [111-22-8], is used as a plasticizer for double-base propellants as a replacement for GTN. One of the many advantages of TEGDN is its insensitivity to detonation. TEGDN is also superior to NG with respect to withstanding cold temperatures under arctic conditions. The oxygen balance is -66.6% for combustion to CO₂ and -27% for combustion to CO.

TEGDN was the main ingredient in an experimental liquid monopropellant NOSET-A:

12.1.1 Production of Triethylene Glycol Dinitrate

TEGDN was first prepared in 1863 by Leurenco. Already during WWII it was used by Germans and Italians as a plasticizer in double-base propellants [518]. TEGDN is manufactured by nitrating triethylene glycol (TEG) under controlled conditions with mixed acid. The difficult point in the production process is treating the spent acid. TEGDN is highly soluble in spent acid (~9%), more so than any of the other commonly made alkyl nitrates, and the mixture is relatively unstable. Safe spent acid treatment is important to ensure safe conditions for TEGDN manufacture. EURENCO Vihtavuori in Finland is using a continuous Biazzi process with a production capacity of 500 kg/h [519].

A modification of common preparation methods allowed for continuous nitration [520]. This procedure recommended the use of sufficient CHFCl₂ to maintain the temperature below 316 K (43 °C = 110 °F) and ensure a safe degree of dilution of the product. The reaction temperature is limited by the boiling point of the refluxing solvent. The triethylene glycol and the mixed acid nitrating agent were separately dispersed in CHFCl₂ prior to mixing. The 74% yield was recovered after evaporation of the CHFCl₂. See also [521].

12.1.2 Physical Properties of Triethylene Glycol Dinitrate

Table 66 shows a comparison of the properties of TEGDN and GTN. Additional physical properties of TEGDN are listed in Table 6, 51, and 67. See also [522, 523].

Table 66: Comparison of physical properties of TEGDN and GTN.

Physical property	TEGDN	Glycerol trinitrate
Molecular mass	240.1	
Solidification point	257.1 or 250.1 K (−19 or −23 °C)	286.3 K (+13.2 °C) stable modification 275.3 K (+2.2 °C) unstable modification
Boiling point	600 K (327 °C) (760 mmHg), calculated, dec.	418 K (145 °C)
Density	1.335 g/cm ³	1.591 g/cm ³
Vapor pressure at 293 K = 20 °C	0.001 mmHg	0.00025 mmHg
Viscosity at 293 K = 20 °C	13.2 cPs	37.8 cPs
Decomposition temperature	501 K (228 °C) (760 mmHg)	323–333 K (50–60 °C) unstable modification 453–473 K (180–200 °C) stable modification
Flash Point	420 K (146.9 °C)	285 K (12 °C)

Data source: [519]

Table 67: Physical properties of TEGDN.

Property	SI units	Other units	References
Molecular mass	240.1681 g/mol	4.1637 mol/kg	[73]
Freezing (glass) point	250 K	−23 °C	Manufacturer's data sheet
Melting point	261.5 K	−11.6 °C	[407]
Density at 298 K/273 K (25 °C/4 °C)	1.3194 g/cm ³		[503]
Density at 293 K (20 °C)	1.335 g/cm ³		Manufacturer's data sheet
Density at 289 K (16 °C)	1.3291 g/cm ³		[10]
Vapor pressure at 303.4 K (30.3 °C)	0.025 Pa	0.188 μm Hg	[503]
Viscosity	0.0132 N·s/m ² at 293 K	13.20 cPs at 20 °C	Manufacturer's data sheet
Viscosity at 279 K (6 °C)		25.7 cPs	[10]
Viscosity at 293.4 K (20.3 °C)		11.9 cPs	[10]
Viscosity at 327.3 K (54.2 °C)		1.5 cPs	[10]
Refractive index n_D^{24}	1.4527		[503]
Refractive index n_D^{20}	1.4540		Manufacturer's data sheet

Vapor pressure data for TEGDN in comparison to the vapor pressures of other glycol polynitrates were already shown earlier in Table 6 and 51.

Like most other nitrate esters, TEGDN tends to supercool on cooling before it crystallizes. It is more accurate to determine a melting point of frozen TEGDN than rely on the freezing point data in the literature. Freezing points listed in the literature are probably the result of substantial supercooling before the sample solidified. The melting point of frozen TEGDN is 248 K (–25 °C) [406]. The heat of fusion of TEGDN is 18 kJ/mol = 75 J/g = 4.3 kcal/mol = 18 cal/g, between that of GTN and BTTN. The visual start- and end-of-melt temperatures for 2-week-old as-received TEGDN crystals were 250.2 and 253.6 K (–22.9 and –19.5 °C), respectively, but 8 months later they had increased to 258.7 and 263.7 K (–14.4 and –9.4 °C), respectively (Table 51 in GTN preceding section).

The vapor pressure of TMETN as a function of temperature can be expressed by the following equation [503]:

$$\log p = A - B/T$$

in which p is the pressure in $\mu\text{m Hg}$, T is the absolute temperature in kelvin, and A and B are constants: $A = 14.4792$ and $B = 4614.7$.

Figure 33 shows an IR spectrum of TEGDN.

Figure 33: IR spectrum of TEGDN. (Reproduced from [296].)

The IR spectra of TEGDN and six other dinitrate esters were computed by a DFT method [297].

A Raman spectrum of TEGDN was compared to Raman spectra of 7 other alkyl nitrates and 24 other explosives as described in [26].

12.1.2.1 Molecular Structure of Triethylene Glycol Dinitrate

A DFT method was used to study the geometric and electronic structures and pyrolysis mechanisms of six dinitrate esters, including TEGDN [297]. The IR spectra of these compounds were obtained and the bands were assigned by vibrational analysis. Based on the principle of statistic thermodynamics, the thermodynamic properties were evaluated, which were linearly related to the number of repetitive $\text{CH}_2\text{CH}_2\text{O}$ groups as well as the temperature, showing good group additivity. Thermal stability and the pyrolysis mechanism of the dinitrate esters were investigated by calculating the BDEs. For the nitrate esters, the $\text{O}-\text{NO}_2$ bond is a trigger bond during a thermolysis initiation process.

12.1.2.2 Thermodynamic Properties of Triethylene Glycol Dinitrate

The thermodynamic properties of TEGDN are summarized in Table 68.

Table 68: Thermodynamic properties of TEGDN.

Property	SI units		Other units		References
Molecular mass	240.1681 g/mol		4.1637 mol/kg		[73]
Enthalpy of formation	-606.3 kJ/mol	-2526 kJ/kg	-144.9 kcal/mol	-603.7 cal/g	[74]
	-628.9 kJ/mol	-2619.2 kJ/kg	-150.3 kcal/mol	-626.0 cal/g	[74]
ΔH_{298}^f	-580.86 kJ/mol		-138.83 kcal/mol		[524]
Heat of combustion	3495 kJ/mol		835.4 kcal/mol		[302]
	3410 kJ/mol	14.57 kJ/g	815 kcal/mol	3483 cal/g	
Heat of evaporation	88.37 kJ/mol	367.9 kJ/kg	21.12 ±	87.94 cal/g	[503]
			0.03 kcal/mol		
Heat of fusion	18 kJ/mol	75 J/g	4.3 kcal/mol	18 cal/g	[406]

12.1.3 Chemical Properties of Triethylene Glycol Dinitrate

The oxygen balance of TEGDN is -66.7%, and the nitrogen content is 11.67 mass-% N.

12.1.3.1 Thermal Stability of Triethylene Glycol Dinitrate

An examination of the thermal decomposition of TEGDN by pressurized DSC showed that at atmospheric pressure, TEGDN had an exothermic decomposition process with a peak temperature of ~489 K (~216 °C) [525]. When the pressure was increased to 2 MPa, the peak shape became very sharp, the peak temperature increased by about 5 °C and shifted from low temperature to high temperature, and the output of the exotherm was over two times that of a peak at atmospheric pressure. If the pressure was increased further, the peak shape, temperature, and exothermic output changed very little.

The thermal behavior and kinetic parameters of the decomposition reaction of TEGDN in a temperature-programmed mode at different pressures (0.1, 2, 4, and 6 MPa) were investigated by DSC and TG-DTG [526]. The results showed that the thermal decomposition of TEGDN was affected by a change in pressure. The kinetic model function, the apparent activation energy E_a , and preexponential factor A of this reaction were $2(1-\alpha)[- \ln(1-\alpha)]^{1/2}$, 106.54 kJ/mol and $10^{9.17} \text{ s}^{-1}$ at 0.1 MPa, and 120.82 kJ/mol and $10^{10.56} \text{ s}^{-1}$ at 2 MPa, respectively. The critical temperature of thermal explosion of TEGDN obtained by the onset temperature and the peak temperature (when the heating rate tends to zero) are 464 and 483 K (191 and 210 °C) at 0.1 MPa and 480.7 and 494.7 K (207.6 and 221.6 °C) at 2 MPa, respectively. On a hot plate with rapid heating, the deflagration point is at 468 K (195 °C = 383 °F).

Quantum chemical computational methods were employed to investigate the equilibrium geometry, frontier orbital energy, and energy gap, as well as the BDEs, of TEGDN and Tetra-EGDN [527]. The thermal stability of two nitrates and the corresponding radicals were analyzed. The calculated O—NO₂ BDEs of TEGDN and Tetra-EGDN were close to the real values. That the experimental thermolysis of two nitrates is only a unimolecular homolytical dissociation of the O—NO₂ bonds is corroborated by the finding that the present results of BDEs were well coincident with the experimental results of activation energies from literature.

12.1.4 Safety Properties of Triethylene Glycol Dinitrate

In the card gap test, confined in a Schedule 40 steel pipe 24.4 mm in diameter and 15 cm long, TEGDN went high order with a velocity detonation of 6400 m/s at zero cards but failed to propagate after only a few inches as soon as a gap of 3.3 mm cards was between the donor and the acceptor charge [528].

When examining the detonation threshold properties of liquid monopropellant NOSET-A, a mixture of TEGDN/dibutyl sebacate/ethyl centralite (96/3/1%) in small-scale detonation and wedge tests, it was concluded that the detonation velocity of the propellant was strongly affected by the sample temperature [529]. For example, when heavily confined at 289 K (60 °F), NOSET-A exhibited a detonation velocity of 5950 m/s; however, no detonation occurred under the same confinement at 271.5 K (29 °F). The detonation pressure of NOSET-A at 285.9 K (55 °F) was 170 kbar, and wedge tests indicated a detonation threshold at 110–130 kbar for transmitted shock pressure.

In the ESD test apparatus, TEGDN was negative at 12.42 nJ. For the adiabatic compression sensitivity of NOSET-A, see [530]. The results were already shown earlier in the IPN section.

12.1.4.1 Toxicity of Triethylene Glycol Dinitrate

TEGDN is as toxic as other nitrate esters like GTN and DEGDN. The toxicological properties of aliphatic nitrates are similar, differing only in intensity, onset, and duration of effect. As of 1983, the completeness of health and toxicity information on three

widely used energetic plasticizers (DEGDN, TEGDN, and TMETN) left something to be desired, and the need for additional research was outlined [531]. Table 69 lists a comparison of toxicity values of TEGDN and GTN.

Table 69: Toxicity of TEGDN and GTN.

Toxicity	TEGDN	References	Glycerol trinitrate
LD50, intraperitoneal, mouse	945 mg/kg	[356]	104 mg/kg
LD50, oral, mouse	1866 mg/kg		115 mg/kg
LD, skin, rabbit	2000 mg/kg		280 mg/kg
LD50, intraperitoneal, rabbit	796 mg/kg	[356]	189 mg/kg
LD50, oral, rat	1000 mg/kg	[356]	105 mg/kg
LD50, subcutaneous, rat	2520 mg/kg	[356]	94 mg/kg

Secondary data source: [519]

Comparing the toxicity of TEGDN and PGDN, it was observed that in most species the LD50 of TEGDN was two to five times as high as that of PGDN [532]. Both compounds produced methemoglobinemia and hypotension in rats. However, TEGDN-poisoned rats trembled violently and expired, apparently in respiratory arrest, after acute convulsive episodes. PDGN-poisoned rats were lethargic and did not convulse. Chronic daily dermal applications to rabbits of 21 mmol/kg of both dinitrates caused death in 2 to 3 weeks. PGDN-treated rabbits gained weight normally, while those treated with TEGDN lost 20 to 30% of their body weight. Guinea pigs receiving as little as 100 mg/kg of TEGDN IP daily had decreased food intake and retarded weight gain. The toxic responses of these two dinitrates are therefore sufficiently different to preclude simple comparisons in hazard evaluations.

12.1.4.1.1 Oral Toxicity of Triethylene Glycol Dinitrate

TEGDN is very toxic. It acts as a violent poison when ingested by rats or as a peripheral nerve block when selectively applied [533]. Dermal application of 21 mmol/kg of body weight in rabbits caused death in 2 to 3 weeks. In a later study, the 24-h IP LD50 in rats was found to be 995 on average, range 932–1063 mg/kg of body weight.

The acute oral median lethal dose (MLD) of TEGDN as measured by an oral gavage single-dose method was 1330 ± 42 mg/kg for male rats and 1116 ± 40 mg/kg for female rats [534] and 2036.5 ± 101.1 mg/kg for male mice and 1866.3 ± 86.2 mg/kg for female mice [535]. Clinical signs included hunched posture, inactivity, tremors, twitching, and hypotonia. Most animals exhibited signs within 2 h after dosing and either they had perished or the signs had cleared by 72 h after dosing.

12.1.4.1.2 Inhalation Toxicity of Triethylene Glycol Dinitrate

A male rhesus monkey was exposed to NOSET-A (which is mostly TEGDN) aerosol for 4 h at a concentration of 2.4 ppm [536]. Visual evoked response and Sidman avoidance task data were collected after 2 h and again after 4 h of exposure. The visual evoked response was not affected, but a significant increase in response rate on the Sidman avoidance task occurred. These data indicated that inhalation of NOSET-A has neurobehavioral effects of potentially serious consequences. NOSET-A was intended as a torpedo propellant.

12.1.4.1.3 Dermal Toxicity of Triethylene Glycol Dinitrate

The acute dermal toxicity of TEGDN was evaluated in rabbits by applying 2 mL TEGDN/kg topically to the clipped dorsal skin surface under a semioclusive wrap for 24 h [537] or by using a modified Draize method [538]. Very slight erythema was observed in eight of eight rabbits and very slight edema in five rabbits 0.5–1 h after dosing. Percutaneous absorption was insufficient to produce any systemic toxicity or death. Several of the rabbits exhibited very slight to slight erythema 0.5 h after wrap removal, and all but one had cleared by 72 h. No other recognizable skin reaction was detected at any time during the 14-d observation period. TEGDN was a mild irritant under conditions of this study. TEGDN has the potential to produce slight dermal irritation, as well as in the eyes [539], but there is no allergic sensitization to repeated skin exposures after the first insult has cleared [540]. Similar tests were conducted with DEGDN.

12.1.4.1.4 Mutagenicity of Triethylene Glycol Dinitrate

The mutagenic potential of TEGDN was assessed using the Ames *Salmonella*/mammalian microsome mutagenicity test [541]. Tester strains TA98, TA100, TA1535, TA1537, and TM538 were exposed to doses ranging from 5 μ L/plate to 0.0016 μ L/plate, in both the presence and absence of metabolic enzyme activation. The test compound was not mutagenic under conditions of this test.

12.1.5 Explosive Properties of Triethylene Glycol Dinitrate

The explosive properties of TEGDN are summarized in Table 70. A thermal stability test at 373 K = 100 °C indicated that TEGDN was considerably less sensitive to temperature than GTN. TEGDN was unaffected in the Bureau of Mines pendulum friction test with a metal or fiber shoe. Impact resistance was much better than for NG. The Bureau of Mines impact test indicated a drop weight sensitivity of over 100 cm. In the BAM impact test machine, beginning reaction was observed at 12.7 N m.

Table 70: Explosive properties of TEGDN compared to GTN.

Explosive property	TEGDN	Glycerol trinitrate
Explosion temperature (5 s)	225 °C	222 °C
Detonation gas volume	1202 L/kg	782 L/kg
Detonation velocity	2000 m/s	7600 m/s
Heat of explosion	725 kcal/kg	1616 kcal/kg
Impact SENSITIVITY (2 kg)	100 cm+ (US Bur. Mines) 43 cm+ (Picatinny Arsenal) 65 cm+ (BAM, Germany)	15 cm
Lead block test	320 cm ³ /10 g	520 cm ³ /10 g
Vacuum stability 100 °C	45 mL in 40 h	least stable of all standard military explosives
Vacuum stability 120 °C	0.8–0.99 mL in 8 h	
Heat test, 100 °C first 48 h	1.8%	3.6%
Heat test, 100 °C second 48 h	1.6%	3.5%
Friction pendulum test, steel shoe	Unaffected	No reaction up to 353 N
Friction pendulum test, fiber shoe	Unaffected	—
Critical diameter (steel sleeve test)	26.7 mm	24 mm
Card Gap test	0.48 cm (0.19 in)	2.31 cm (0.91 in)

Data source: [519]

12.1.5.1 Detonation Properties of Triethylene Glycol Dinitrate

In the lead block test, the explosion of TEGDN caused an increase in the cavity volume by 320 cm³/10 g. TEGDN is relatively insensitive to detonation. In some tests, TEGDN failed to detonate with a No. 8 blasting cap. No detonation occurred in samples placed in light steel tubing with a diameter of 3.175 cm at a density of 1.33 g/cm³. When heavily confined, the detonation velocity was less than 2000 m/s.

In the NOL card gap test, TEGDN was tested in comparison to RDX, C-4, and an NC/TEGDN/AP/Al solid propellant [542]. With heavy confinement (steel pipe), the critical diameter was 26 D_c 35 mm (1.05 D_c 1.38 in.) and the NOL card gap sensitivity 50% point was at 57 cards.

A DFT method was used to predict the explosive performance of six dinitrate esters, including TEGDN [297]. Detonation performances were evaluated by the Kamlet-Jacobs equations based on the calculated densities and heats of formation. It was found that density, detonation velocity, and detonation pressure decreased with increases in the number of CH₂CH₂O groups. The predicted detonation velocity of TEGDN at a density of 1.55 g/cm³ was 7.25 km/s, and the detonation pressure was 21.23 GPa, compared to 8.96 km/s and 35.03 GPa for EGDN.

12.1.6 Propellant Mixtures with Triethylene Glycol Dinitrate

TEGDN is widely used as a plasticizer for double-base propellants and Composite Modified Double Base (CMDB) propellants.

NOSET-A consisted of 96% TEGDN, 3% di-*n*-butyl sebacate as desensitizer, and 1% ethyl centralite as stabilizer. The vapor pressure of NOSET-A at 298 K was 0.33 Pa (0.0025 mm Hg). The nominal density of NOSET-A at 298 K was 1.31 g/cm³.

12.2 Trimethylolpropane Trinitrate

1,1,1-Trimethylolpropane trinitrate, also known as 2-ethyl-2-(hydroxymethyl)-1,3-propanediol trinitrate, C₆H₁₁N₃O₉, H₃CCH₂C(CH₂ONO₂)₃, TMPTN, CAS RN [2921-92-8P], can be prepared by the nitration of 1,1,1-trimethylolpropane with nitric acid [543]. Using 98% nitric acid as the nitrating reagent, with a molar ratio of trimethylolpropane to nitric acid of 10:1, a reaction time of 2h, and a reaction temperature of 0–20 °C, the yield of TMPTN reached as high as 99.7%. The product was characterized by IR, NMR, and elemental analysis.

12.2.1 Physical Properties of Trimethylolpropane Trinitrate

The physical properties of TMPTN and its lower homolog, TMETN, are compared in Table 71.

Table 71: Physical properties of TMETN and TMPTN.

Compound name	Trimethylolethane trinitrate TMETN	Trimethylolpropane trinitrate TMPTN
Gross formula	C ₅ H ₉ N ₃ O ₉	C ₆ H ₁₁ N ₃ O ₉
Molar mass	255.1397 g/mol 3.919 mol/kg	269.4 g/mol 3.712 mol/kg
Oxygen balance	–34.5%	–50.5%
Density at 293 K	1.47 g/cm ³	1.5 g/cm ³
Melting point	270 K = –3 °C	324 K = 51 °C
Enthalpy of formation	–1739 kJ/kg = –443.7 kJ/mol	–1783 kJ/kg = –480.3 kJ/mol

The heat of combustion at a constant volume of 1,1,1-tris(hydroxymethyl)propane trinitrate is 3469 kJ/mol = 829.2 kcal/mol, and that of its parent triol, 1,1,1-tris(hydroxymethyl)propane, is 3613 kJ/mol = 863.5 kcal/mol [544].

12.2.2 Thermal Stability of Trimethylolpropane Trinitrate

The thermal decomposition of TMPTN was investigated by high pressure DSC [545, 546]. It was shown that even though the structure of TMPTN is similar to that of NG and TMETN, the thermal decomposition characteristics of TMPTN are different from those of NG and TMETN. TMPTN began to decompose at 409.9 K (136.8 °C). At normal

pressure, the DSC curve of TMPTN had two peaks: one was a melting endothermic peak ($481\text{ K} = 208^\circ\text{C}$ at $10^\circ\text{C}/\text{min}$) and the other was an exothermic decomposition peak, while NG had only an endothermic peak and TMETN had an exothermic decomposition peak, without a melting endothermic peak. At high pressure, TMPTN had two similar peaks, but the melting endothermic peak was not evident compared to that at normal pressure. The shape, temperature, and quantity of heat of decomposition peak greatly changed with different pressures. The peaks were broad at 101 kPa but became sharp at 7 MPa. The activation energy of TMPTN decomposition at 101 kPa was 181.1 kJ/mol .

12.3 Other Polynitrate Esters

Theoretically cellulose polynitrate, nitrocellulose would belong in this chapter, but the properties of nitrocellulose will be postponed to future volumes of the *Encyclopedia of Rocket Propellants* in conjunction with double-base propellants and the ingredients for making double-base propellants. Similarly, dextrin nitrate and polydextrin nitrate will be treated in future volumes.

PETN is primarily used as an explosive and not as a propellant. For this reason it was not included in this book. Its properties have frequently been cited in comparison to other propellant ingredients, but it is not covered in its own section in this book. The same applies to several other primary explosives.

The nitration of tris(hydroxymethyl)aminomethane (Tris) gives a group of energetic nitrates [547]. The new nitrates were fully characterized by NMR, IR, MS, DSC, and elemental analysis. The structure of each compound was confirmed by single-crystal XRD. The energies of formation were calculated with the Gaussian program package, and the detonation parameters were predicted using EXPLO5 computer code. Because of the positive oxygen balance of these compounds, their performance data as oxidizers were compared to the common oxidizer ammonium perchlorate.

12.3.1 Nitroalkyl Nitrate Esters

2,2-Dinitro-1,3-bis(nitroxy)propane, also known as $\text{O}_2\text{NOCH}_2\text{C}(\text{NO}_2)_2\text{CH}_2\text{ONO}_2$, $\text{C}_3\text{H}_4\text{N}_4\text{O}_{10}$, dinitropropyldinitrate, DNPN (not to be confused with NPN for *n*-propyl nitrate), is a candidate energetic plasticizer because of its high oxygen balance (+12.5%) and low T_g ($191.5\text{ K} = -81.5^\circ\text{C}$, midpoint) [548]:

However, the thermal stability of DNPN has been insufficient and the search for a suitable stabilizer for DNPN is ongoing.

A castable polynitrate ester, tentatively identified as 2-nitratomethyl-2-nitro-3-nitratomethyl-3-nitro-butane(1,4)diol dinitrate, was prepared in a three-stage

synthesis [549]. Compared to PETN, it had a relatively low melting point, which makes it suitable as a castable explosive. It had a density of 1.917 g/cm³ and a melting point of 358–359 K (85–86 °C). The heat of formation was measured to be –371 kJ/mol by combustion bomb calorimetry. The predicted detonation velocity was 9.1 km/s (similar to HMX), and the predicted detonation pressure was 40 GPa:

2-nitratomethyl-2-nitro-3-nitratomethyl-3-nitro-butane(1,4)diol dinitrate

The heat of combustion at constant volume of 2-ethyl-2-nitro-1,3-propanediol dinitrate, $\text{O}_2\text{NOCH}_2\text{C}(\text{NO}_2)(\text{C}_2\text{H}_5)\text{CH}_2\text{ONO}_2$, is 2902 kJ/mol = 693.5 kcal/mol, while that of its parent diol, 2-ethyl-2-nitro-1,3-propanediol is 2944 kJ/mol = 703.7 kcal/mol [544].

12.3.2 Fluoroalkyl Nitrate Esters

The oxygen balance of energetic plasticizers can be improved by replacing some of the hydrogen in the alkyl groups with fluorine or azido groups. Fluoroalkyl nitrate derivatives have higher densities, better thermal stability, and lower shock sensitivity than the all-hydrogen analogs. Thermally stable energetic plasticizers have been synthesized that contain terminal fluoroalkyl groups. Alkyl nitrate esters with terminal trifluoromethyl groups have good thermal stability and good energy content. These compounds are of interest as replacements for dinitrato propane in Otto Fuel II or as plasticizers in double-base propellants or PBX explosives.

12.3.3 Difluoroaminoalkyl Nitrate Esters

Energetic plasticizers containing 3,3-bis(difluoroamino)-1,5-(dinitrato)pentane (BFDNP) have a T_g of around 186 K (–87 °C) and an onset of exothermic decomposition at 459 K (186 °C) and can be used as improved plasticizers with excellent performance potential [550].

12.3.4 Azidoalkyl Nitrate Esters

The oxygen balance of energetic plasticizers can be improved by replacing some of the hydrogen in the alkyl groups with azido groups. Azidoalkyl nitrate derivatives have higher densities and more energy than the all-hydrogen analogs. Thermally stable en-

ergetic plasticizers have been synthesized that contain terminal azido groups in addition to nitrate ester groups.

These compounds could just as well be treated in the chapter on organic azide compounds (*Encyclopedia of Liquid Fuels*, "Azido Compounds"), but the primary location is here under alkyl nitrates. Both the nitroxyl group and the azido group are very active. Usually we file these multi-substituent compounds under the group that is more reactive. In this case, the two groups seem to be equally reactive (and will cause premature decomposition of many energetic materials).

12.3.4.1 Pentaerythritol Diazido Dinitrate

PETN is a well-characterized energetic material. In the search for liquid energetic materials with lower melting points than PETN, a group of azidoalkyl nitrates was investigated. Most emphasis was placed on characterizing pentaerythritol diazido dinitrate as an energetic plasticizer [551, 552].

Pentaerythritol diazido dinitrate, $\text{O}_2\text{NO}-\text{CH}_2-\text{C}(\text{CH}_2\text{N}_3)_2-\text{CH}_2-\text{ONO}_2$, $\text{C}_5\text{H}_8\text{N}_8\text{O}_4$, 1,3-dinitroso-2,2-diazidomethyl-propane, is a colorless oil. It has an oxygen balance of -46.35% and a nitrogen content of 40.57%.

Diazido derivatives of pentaerythritol can be prepared by reacting 3,3-bis(azidomethyl) oxetane with inorganic acids such as hydrobromic or nitric acid [553]. The resulting diazido monobromide can be reacted with sodium azide to produce pentaerythritol triazide, which can be subsequently nitrated to pentaerythritol triazido mononitrate. The pentaerythritol diazido mononitrate produced by the reaction of nitric acid with the aforementioned oxetane can be further nitrated with nitric acid to produce pentaerythritol diazido dinitrate, a thoroughly investigated energetic compound. These diazido and triazido derivatives of pentaerythritol can be utilized as energetic azido plasticizers *per se* or can serve as intermediates for the production of such plasticizers. Pentaerythritol triazido mononitrate is an intermediate product, but it can also be used by itself as is. The pentaerythritol diazido mononitrate produced by the reaction of nitric acid with the aforementioned oxetane can be further nitrated with nitric acid to produce pentaerythritol diazido dinitrate. Pentaerythritol diazido monobromide can be reacted with sodium azide to produce pentaerythritol triazide, and the latter can be subsequently nitrated with nitric acid to produce pentaerythritol triazido mononitrate, as noted below:

Pentaerythritol diazido mononitrate can be further nitrated with nitric acid to produce the desired pentaerythritol diazido dinitrate as shown here:

Pentaerythritol diazido dinitrate is a low-melting-point substance, depending on the purity, with a density of 1.507 g/cm^3 and a refractive index of $n_D^{22.5}$ of 1.5161. Later reports using a different method of synthesis obtained a purer product that melted at 312.7 K (39.6°C) [554]. The heat of combustion is 14259 J/g , and the enthalpy of formation is $+825.42\text{ kJ/mol}$.

A different technique of preparing pentaerythritol diazido dinitrate (PDADN) proceeded via bromidation reaction of pentaerythritol as the starting material, azidation of 2,2-bromomethyl-1,3-propanediol, and nitration of 2,2-azido-1,3-propanediol [555]. The structure of PDADN was characterized by IR, ^1H NMR, and elemental analysis.

The thermal decomposition of PDADN was examined using TGA, DSC, pressure DSC, and rapid scanning FTIR spectroscopy [556]. The results showed that **(1)** the extrapolated onset temperatures, peak temperatures, and enthalpy of decomposition increased with a change in pressure from 0.1 to 2 MPa. Over the range of pressures from 2.0 to 6 MPa, the thermal behavior of PDADN did not seem to be very affected by the pressure; **(2)** the apparent activation energy and the preexponential constant of thermal decomposition of PDADN at a pressure of 0.1 MPa were 134.9 kJ/mol and $10^{12.7}\text{ s}^{-1}$, respectively; and **(3)** the pressure affected the magnitude of the apparent activation energy.

The structure of PDADN was studied by FTIR, MS, and NMR [557]. The molecular geometries and electronic structures of the four conformations of PDADN were fully optimized using a semiempirical AM1-MO method [558]. Among the four conformations, the structure with one $-\text{ONO}_2$ group at *trans* conformation and another $-\text{ONO}_2$ and two $-\text{N}_3$ groups at *cis* conformations was the most stable. When all four groups, two $-\text{ONO}_2$ and two $-\text{N}_3$, were at *trans* conformations, the nuclei repulsion energy was lower, and the dipole moment was smaller than those in other conformations.

The molecular geometries, electronic structures, and IR spectra at the four conformations of pentaerythritol diazido dinitrate were calculated using a DFT B3LYP method [559]. Among the four conformations, the one whose structure consisted of one $-\text{NO}_2$ group at the *cis* position and the other $-\text{NO}_2$ group and two $-\text{N}_3$ groups at the *trans* position was the most stable. The calculated IR absorption band frequencies of $-\text{NO}_2$ groups and $-\text{N}_3$ groups in the IR spectra were in agreement with the corresponding experimental data.

The thermal decomposition of PDADN was investigated by DSC-TGA-FTIR [560]. The time-resolved TGA-IR curves of the change of the IR characteristics and relative absorption intensity of decomposition gas products as a function of temperature yielded the kinetic parameters and mechanism functions of PDADN decomposition.

The mechanism of PDADN thermal decomposition was analyzed based on the *isokinetic point* of the formation rate among all the decomposition gas products.

Five structurally similar $-\text{ONO}_2$ and $-\text{N}_3$ derivatives of pentaerythritol, including tetraazido pentaerythritol (TAPE), pentaerythritol triazido nitrate (PTAN), PDADN, pentaerythritol azido trinitrate (PATN), and PETN were studied by a molecular orbital computational method [561]. The molecular geometric configurations were optimized, and vibration analyses were conducted, and the densities, heats of formation, thermodynamic functions, detonation performances, and specific impulses were calculated. The BDE of the possible trigger bond and the activation energy of the hydrogen transfer reaction were computed. The results showed that in comparison with PTAN, PDADN, PATN, and PETN, TAPE has the highest heat of formation among the five derivatives and a specific impulse level approaching that of PETN. The detonation performance and stability of PATN were close to those of PETN and better than that of other derivatives, including PDADN. The pyrolysis of TAPE is most likely initiated from the transfer of H to $-\text{N}_3$, which leads to the elimination of N_2 , and has an E_a of 130.57 kJ/mol. The pyrolysis of other derivatives containing $-\text{ONO}_2$ groups most likely starts from the rupture of the $\text{O}-\text{NO}_2$ bond with a BDE of 130.91–137.45 kJ/mol. These energy values satisfy the common stability requirements for these energetic compounds.

12.3.4.2 1,3-Diazido-2-nitroxypropane

1,3-Diazido-2-nitroxypropane, also known as 1,3-diazidopropan(2)ol nitrate, 1,3-diazido-2-nitryloxypropane, DANG, $\text{N}_3\text{CH}_2\text{CH}(\text{ONO}_2)\text{CH}_2\text{N}_3$, $\text{C}_3\text{H}_5\text{N}_7\text{O}_3$, is an energetic plasticizer that has not yet found any application. It has an oxygen balance of -47.04% and a nitrogen content of 52.34% . Its freezing point is below 258 K (-15°C), and its density is 1.0059 g/cm^3 at 293 K. The onset of thermal decomposition exotherm is at 461 K (188°C) [562]. 1,3-diazido-2-nitroxypropane can be prepared with 1,3-dichloro-2-propanol as starting material via azidation and nitration with 1,3-diazido-2-propanol as an intermediate [563, 564].

12.3.4.3 1,3-Diazido-2,2-dinitroxypropane

1,3-Diazido-2,2-dinitroxypropane, also known as neopentyl glycol diazido dinitrate, $\text{N}_3\text{CH}_2\text{C}(\text{CH}_2\text{OONO}_2)\text{CH}_2\text{N}_3$, was synthesized by a one-pot process, which consisted of two steps, i.e., nucleophilic substitution of 1,3-dibromo-2,2-dihydroxymethylpropane with sodium azide and nitration of the substituted intermediate (1,3-diazido-2,2-dihydroxymethylpropane) with nitric acid, but carried out in one pot without separating the intermediate [565]:

The factors affecting the yield and purity of neopentyl glycol diazo dinitrate, such as the ratio of 1,3-dibromo-2,2-dihydroxymethylpropane/sodium azide/nitric acid, nitration temperature, and time, were optimized. The optimized process conditions were as follows: 1,3-dibromo-2,2-dihydroxymethylpropane/sodium azide/nitric acid (molar ratio) = 1.0/2.1/8.0, $T = 268\text{--}292\text{ K}$ ($15\text{--}19\text{ }^{\circ}\text{C}$), and $t = 18\text{ min}$. The yield and purity of the resulting neopentyl glycol diazo dinitrate could be up to 84 and 98%, respectively, and the structure was identified with IR, NMR, and elemental analysis.

Nitrate Oxidizers

1 Introduction – Solid Nitrate Oxidizers

Like any oxidizer for rocket propellants, oxidizers for solid propellants need to have a high percentage of excess oxygen. However, while in the case of liquid oxidizers the lack of excess oxygen can be adjusted by changing the oxidizer-to-fuel liquid propellant flow rates, that choice is not available for solid propellants. This is because the binder that holds the oxidizer granules together is generally an organic fuel type that can hold only a limited amount of solids before its mechanical properties deteriorate and it cracks under the load of acceleration during transportation and launch. One of the key parameters characterizing a solid propellant is the *percent solids loading*. For optimum performance, there has to be at least sufficient oxidizer to achieve complete combustion of the binder to CO, water, and nitrogen. High-density oxidizers allow more binder to be used, resulting in better mechanical properties.

The oxidizers for solid propellants are mostly the perchlorates and nitrates of ammonium compounds. Alkali metal perchlorates [1] and nitrates may be used for pyrotechnic igniter charges, but they are rarely used in modern rocket propellants because the high molecular mass and the particulate nature of the alkali metal oxides in the exhaust lowers the specific impulse. Solid propellants for model rockets and toy rockets may still use potassium nitrate in formulations similar to the old “black powder” that has been used for almost 1000 years. In the past 20 years, two new oxidizing anions have been added to the inventory: dinitramide (dinitramidate) and nitroformate. They can be combined with ammonium, hydroxylammonium, hydrazinium, or heterocyclic cations to form solid salts. These new oxidizers were not included in older books on rocket propellants, and the current book at hand provides the first comprehensive summary on the properties of these new oxidizers.

Discussions about the production of various solid-propellant oxidizers are contained in the following sections on individual oxidizers, usually as one of the very first subsections of each section. While most other industrial applications of these chemicals are not affected by the particle (crystal) size and shape, these properties do affect the processability and burning rates of solid propellants and need to be carefully controlled. If a solid-propellant oxidizer in the as-supplied state does not have the desired particle size or shape, it will have to be recrystallized or ground (pulverized) to the required size. A very useful chapter on the crystallization of chemicals with special reference to solid-propellant oxidizers is contained in [2]. It includes nicely illustrated information on the best crystallization methods for ammonium nitrate (AN), ammonium dinitramide (ADN), hydrazinium nitroformate (HNF), 3-nitro-1,2,4-triazole-5-one (NTO), hexanitrohexaazaisowurtzitane (CL-20), and many other energetic materials. For

instance, the crystal shape of various energetic materials can be changed in the desirable direction by changing the solvent and the cooling rate. Ultrasound might be used during crystallization to induce nucleation at lower supersaturation levels. Quite often the optimum solids loading of solid propellants can be achieved only with bimodal or even multi-modal particle size distribution of the oxidizer.

During the past two decades, development in the field of solid-propellant oxidizers was driven not only by the need for higher specific impulse but also by the desire to reduce air pollution from toxic rocket-propellant exhaust such as HCl and AlOCl . Chlorine-free, environmentally-friendly oxidizers have received a lot of attention but are still several steps away from practical application.

1.1 Comparison of Solid-Propellant Oxidizers

The properties of solid-propellant oxidizers are summarized in Table 1. The most important evaluation criterion for any oxidizer, solid or liquid, is the percentage of oxygen available for the combustion of a fuel the oxidizer is paired with in a rocket-propellant formulation. One can express the percentage of available oxygen as weight (mass) percent, as oxygen balance, or as the oxygen deficiency number, which in the case of oxidizers actually is an oxygen excess number, so it carries a positive instead of a negative sign. If the oxidizer contains a halogen in addition to oxygen, the halogen also has oxidizing potential and can be added to the oxygen balance (a formality), but one will need to explain how the oxygen balance was calculated (with or without inclusion of the halogen).

Table 1 contains a column for available oxygen, expressed in mass-%. In most cases this number is smaller than the total oxygen content because some of the oxygen may be consumed by the cation if it contains metals or hydrogen. In the case of alkali metal perchlorates, it is safe to assume that the halogen will bond with the alkali metal to form an alkali metal halide; thus, all oxygen should be available. In the case of perchlorates of nitrogen-hydrogen cations such as ammonium and hydrazinium, extra credit should be given in the available oxygen column for the chlorine, which can bind some of the hydrogen. This is indicated by the designation (+ Cl).

Table 1: Useful oxygen content and physical properties of solid oxidizers.

Compound name	Formula	Molec- ular mass, g/mol	Total oxygen content, mass-% O	Available oxygen, mass-% O	Melting point		Density, g/cm ³ , at °C	Enthalpy of formation	
					K	°C		kJ/mol	kcal/mol
Lithium nitrate	LiNO ₃	68.94	69.62	58.02	525	252	2.38 (25°)	-482.4	-115.3
Lithium perchlorate	LiClO ₄	106.39	60.15	52.64 (+ Cl)	512	239	2.429	-380.3 ± 1.2	-90.89 ± 0.29

2 Ammonium Nitrate

There is increasing interest in the development of ecologically-friendly solid-propellant systems that can replace the existing ones in applications, particularly when the rockets have to be fired in close proximity of military personnel and smokeless HCl-free burning is desired. Avoiding HCl in the exhaust will lead to cleaner burning propellants with no contrail and low signature, thus not revealing the launch site to the enemy. Therefore, ammonium nitrate (AN) is receiving renewed attention as a possible substitute for ammonium perchlorate (AP) oxidizer in view of the hazardous nature of other candidates such as nitramines and the non-availability of substances such as ammonium dinitramide in requisite quantities and at affordable prices. With an oxygen balance of +19.99%, AN is a moderately good oxidizer for solid rocket propellants, and it is not at the top of the list when it comes to evaluating solid oxidizers based on their useful oxygen content alone.

Although ammonium and hydrazinium nitrates and perchlorates can burn by themselves if the decomposition is accelerated by burning rate additives, using AN by itself does not offer any advantages over formulations that contain organic binders. The strand-burning decomposition of pure hydrazinium salts can spontaneously transition into a detonation. In addition to the complications caused by polymorphism and phase changes, AN is very hygroscopic, and if stored in bulk, it has a tendency to cake. For the various applications of AN, what the industry wants is a free-flowing granular material. For this reason, AN intended to be used as a fertilizer is often prilled in spherical form (melt spraying) and coated with anti-caking agents. Anti-caking agents often used include clay, zeolites, diatomaceous earth, and aluminosilicates. Anti-caking agents may interfere with the intended applications of AN in rocket propellants, gas generants, or explosives.

Because AN is an important propellant and explosive ingredient and industrial bulk commodity, several conferences and literature summaries have been devoted exclusively to this chemical [3–5].

2.1 Natural Occurrence of Ammonium Nitrate

Ammonium nitrate occurs naturally as an intermediate product during the bacterial oxidation of ammonia. The nitrification by nitrifying bacteria that occurs in the soil where aqueous or gaseous ammonia has been applied as fertilizer in the field is undesirable because nitrate is leached by rain or irrigation water and carried away faster than ammonia, which remains adsorbed to clay in the soil until it is taken up by the roots of the plants. Ammonium nitrate can form naturally in sewage and other nitrogen-rich environments. Aerosols of AN and ammonium sulfate form in polluted air and play a significant role in atmospheric smog chemistry. Much of the natural nitrogen fixation in the form of NO_x is the result of atmospheric lightning electrical

discharges. The formation of AN in a model nitrogen atmosphere containing oxides of nitrogen, ammonia, water vapor, and oxygen present in parts-per-million (ppm) quantities has been investigated [6]. The measured amounts of nitrate produced were compared with those predicted by use of a kinetic model for the reacting system. For any temperature, there was an initial pressure of ammonia below which AN was not found. At higher pressures of nitrogen dioxide, equilibrium was quickly attained, but at low pressures, nitrate was not always formed in the time of contact of reactants. Water vapor enhanced the rate of formation of nitrate.

2.2 Production of Ammonium Nitrate

Ammonium nitrate, NH_4NO_3 , AN, CAS RN [6484-52-2], is a bulk industrial production chemical [7]. It is produced industrially in large quantities by neutralization of aqua ammonia or anhydrous ammonia gas with diluted or concentrated nitric acid. This neutralization reaction is violent and very exothermic and has led to accidental explosions [8]. Of course, the combination of anhydrous ammonia and white fuming nitric acid could be used as a bipropellant rocket combination. For making solid AN, after the solution is formed, typically at about 83% concentration, the excess water is evaporated to an AN content of 95 to 99.9% concentration (AN melt), depending on purity grade and intended application. The AN melt can then be made into “prills” or small beads in a spray tower or into granules by spraying and tumbling in a rotating drum. The prills or granules may be further dried and are cooled and then coated to prevent caking and moisture absorption. These prills or granules are the typical AN products in commerce.

Of all AN produced from nitric acid, the majority (86%) is used in the nitrogen-based fertilizer industry, either as a direct fertilizer or in the production of fertilizer blends with ammonium sulfate or urea ammonium nitrate. In looking at the usage statistics, after the demand of the fertilizer industry is accounted for, the balance of the AN derived from nitric acid is used mainly for manufacturing explosives and blasting agents (“ANFO”; ammonium nitrate–fuel oil mixture). Relatively little AN is used in rocket propellants or gas generants.

2.2.1 Crystallization of Ammonium Nitrate

Crystallization of AN can occur either from saturated solutions or from the melt. For propellant applications, it is very important to obtain water-free AN in the desired particle size and phase. Quite often, phase-stabilizing additives are co-crystallized with the AN. Therefore, the crystal growth habits of AN by itself and AN with additives have been investigated. The growth rate of NH_4NO_3 phase III crystals from saturated solutions was measured and interpreted using two models: The first was a standard crystal growth model based on a spiral growth mechanism, and the second was based on

the new concept of kinetical roughening [9]. As the crystal surface becomes rough, a critical supersaturation point can be determined, and from this step a value for the free energy can be derived. Another model for the morphology of phase III AN crystals was based on the concepts of periodic bond chain, F face, and a connected net of ions [10].

Much of the phase behavior of AN is influenced by how it is crystallized the first time. Changes in the crystal structure of freshly crystallized AN take place for several hours after the material has first solidified. By examining freshly crystallized AN using scanning electron microscopy (SEM), it was observed that aging for >1 h led to the growth of secondary grains along the boundaries of primary grains (140–200 μm) [11]. After 6 h of aging, no more grain growth along grain boundaries could be observed. Instead, distinct clusters with morphologies similar to the secondary grains were formed. The secondary growth occurs to relieve strain at the grain boundaries and to minimize interfacial tension between the grains.

The AN crystal shape depends on the conditions of cooling and supercooling and the presence of seed crystals or nuclei. It was possible to crystallize phase I and phase II AN as dendrites from a melt containing 0–4.5 and 4.5–12 mass-% water, respectively [12]. *In situ* microscopic measurements showed that the characteristic ratio S/ρ (where S is the side branch spacing near the tip and ρ is the dendrite tip radius) for dendrites varies between 2.3 and 5.1 for both AN(I) and AN(II). This agreed reasonably well with a theoretically derived value of 2.8 reported in the literature. The water concentration had a strong influence on the crystal shape as expressed by the relation between the side-branch spacing near the tip, S , and the tip growth rate, v , of the dendrites. These observations matched, at least qualitatively, the theoretically predicted relationship between S and v . Ammonium nitrate phase II crystals growing from an AN solution containing 5.7 mass-% water develop as dendrites in the ab -plane and in the c -direction and are referred to as ab - and c -dendrites, respectively. Experimental data have suggested that the growth form of the ab -dendrites growing in pure aqueous solutions results from the instability of the growth directions along the a - and b -axes and can be altered by the presence of additives [13, 14]. If the growth rate of c -dendrites is sufficiently retarded by additives, the ab -dendrite tips are stable, do not split, and grow along the a - and b -axes. If side branches growing in the c -direction are less retarded, the ab -dendrites show tip splitting, finally resulting in growth directions deviating from $\langle 100 \rangle$ and being approximately $\langle 410 \rangle$. The tip growth rates as well as the side branch spacings depend on the amount of undercooling.

Ammonium nitrate nanoparticles can be made by employing a surfactant templating method [15]. For example, about 10 g bulk AN is dissolved in 10 mL deionized water. About 2 mL PEG-400 is added to this solution, and the solution is thoroughly mixed. This solution is kept in an oven at 333 K (60 °C) for several hours to slowly evaporate the water. The resultant material is then stirred vigorously while adding 2-propanol from a burette at a rate of 1 mL/min, which forms a white precipitate that

is then washed with excess 2-propanol several times to remove almost all of the PEG-400. The precipitate is then dried completely at 333 K (60 °C) to obtain a dry powder. Ammonium nitrate is highly hygroscopic, so these nanoparticles tend to recrystallize to form bulk crystals. Therefore, it is best to keep AN nanoparticles in a vial sealed under vacuum to prevent moisture absorption.

2.2.2 Prilling of Ammonium Nitrate

AN is often converted to the desired particle shape by spraying and atomizing molten AN (with or without the addition of phase-stabilizing additives) into a tall tower, where the falling droplets assume a spherical shape before they solidify and are carried away by a cooling gas stream. The operating temperature during this prilling process must be carefully controlled to ensure that all AN is molten yet not overheated to the point of incipient decomposition. Prilling produces a range of particle sizes from 20 to 400 μm . The prilled and coated near-spherical particles have the advantage that they are free flowing, which makes it easier to transfer fertilizer grade AN from storage silos to hopper cars and fertilizer spreaders. Supercooling of droplets in the prilling tower must be avoided. Therefore, nucleating (seed) agents are added to avoid supercooling of the melt and to initiate crystallization. Aluminum silicate and silica have been tested as nucleating agents. In addition, 1% fumed silica or tricalcium phosphate can be applied as an anti-caking agent. All of these must be expected as contaminants if industrial-grade AN is to be used for propellants.

Freshly prepared prills flow freely; however, the phase IV $\leftrightarrow$ phase III phase change during storage and transport causes the prills to fracture and fragment. The benefit of coatings (e.g., anti-caking or hydrophobic coating) of the prills is forfeited once they fracture and uncoated surface is exposed. If only 10% of the spherules fracture, the benefit of coatings is lost, and the bulk material is likely to set up into a monolithic mass. If the prills run through several phase-transition cycles, they convert to powder, which is more likely to form a monolithic cake that is hard to remove and disperse. The addition of phase stabilizers to AN is therefore of importance not only for AN as a rocket propellant and gas generant but also for most other applications of AN.

A different process used for both AN and ADN is the prilling by spraying droplets of molten salts into a stirred pool of an inert, cool liquid in which the droplets can assume a spherical shape before they solidify. This process can be applied to a wide range of energetic materials as well as AN and ADN [16, 17].

For optimum packing in a solid propellant grain, it is best to use spherical oxidizer particles. Besides the spraying of molten AN into a prilling tower, spheres can be shaped by melting AN in a two-phase system. In this case, the molten AN is dispersed in a continuous, inert phase that is not miscible with AN. The surface tension and interfacial tension cause the molten droplets to assume a spherical shape. The solidification of the molten droplets to spherical prills takes place during the cooling

to a temperature below the melting point of AN. By proper choice of suitable oil-bath fluids and spray nozzles and by optimizing the process parameters, spherical AN particles with mean particle sizes from 10 to 800 μm can be manufactured reproducibly, similar to a process used for ADN [18–22]. The inert fluid prilling process consists of two stages: In the first stage, molten AN is dispersed in a continuous phase in which AN is insoluble. The droplet size produced can be controlled by varying the force of agitation. The influence of the different process parameters, such as dispersion rate, dispersion power, emulsification time, influence of emulsifying agents, and the rheological behavior of the continuous phase were studied to optimize the process. In the second stage of the process, crystallization of the emulsified AN droplets to spherical, solid particles is obtained by quickly lowering the temperature of the system. This process also gives spherical AN particles with mean sizes of 10–800 μm . Fumed silicon dioxide can be used as a protective colloid to promote emulsification.

Instead of producing prilled stabilized AN in a batch process, it is possible to conduct this as a continuous process with adequate process controls for a reproducible product [23, 24]. Similar continuous processes have been developed for the prilling of ADN.

Prilled and stabilized AN is of interest as a propellant ingredient for gas generants in airbag inflators [25]. However, failure to prevent intrusion of moisture into the gas generators or insufficient desiccant in the cartridge allowed phase changes to take place and caused numerous fatalities in airbag inflator explosions.

2.2.3 Coating of Ammonium Nitrate

Ammonium nitrate is often coated to reduce its hygroscopicity, to prevent it from caking, and to achieve a better bond with the solid-propellant binder.

A systematic study has been made of the interaction mechanisms of amine type surfactants and AN by using X-ray diffraction (XRD) and X-ray photoelectron spectroscopy (XPS) [26]. The results indicated that octadecylamine adsorbs on the surface of powdered AN in the form of octadecylammonium nitrate. Bromo-hexadecyltrimethylamine also adsorbs on AN through rather strong chemical affinity action, providing a good anti-caking effect of amine-type surfactants on powdered AN.

Octadecylamine at a concentration of 2×10^{-4} mol/L in xylene was selected as a monolayer-forming material to coat AN crystals [27, 28]. After a self-assembling monolayer was formed through hydrogen bonding, Coulomb forces, and polarization at the interface of xylene and AN, a monolayer of octadecylamine is assumed to have self-assembled itself on the surface of AN crystals. The rate of moisture absorption of AN after surface modification was only 58% of that of untreated AN.

Ammonium nitrate was coated with a wetting agent Si-K and polymer material Polymer B [29]. Surfaces of the coated AN particles were characterized by SEM and XPS. The hygroscopicity and caking tendency of the coated AN were measured, and

the experimental results showed that the hygroscopicity and caking tendency of AN particles could be effectively reduced through this type of coating.

A liquid-phase separation technique was used to coat AN with polyvinyl butyral (PVB) [30]. A study of the properties of coated AN showed that the water absorptivity and caking tendency were greatly reduced. The differential scanning calorimetry (DSC) peak of the crystal phase transition of II $\rightarrow$ III shifted to higher temperature and even disappeared.

A polymer and a wetting agent were used to coat phase-stabilized AN (PSAN) by means of a spraying and drying technique in order to lower the moisture absorption of AN [31]. The characterization of the modified PSAN was performed by measuring the hygroscopicity, contact angle, and mass fraction of the coating layer and by using XPS and SEM. The results showed that the composite modification of both the polymer and the wetting agent can effectively reduce the moisture absorption of PSAN by up to 46%. This indicated that spraying and drying technology is better than liquid-phase separation coating techniques.

The crystal properties of AN modified by treatment with surfactants were analyzed by SEM, DSC, and XRD, and their specific surface area, hygroscopicity, caking, and explosion properties were examined [32]. The results showed that, compared to conventional AN, the modified AN crystals have different shapes and larger specific surface areas. They contain a larger number of gas pockets, but they are also less hygroscopic and have less tendency to cake, which are desirable properties for all explosive applications.

AN particles were coated with polyvinyl acetate and ethyl cellulose in order to improve wetting between AN particles and the binder [33]. This was done to prepare AN-based propellants with higher solids loading by the use of coated AN.

To decrease the surface polarity and hygroscopicity of AN, a surfactant, a wetting agent, and a polymer were used to coat AN particles [34]. A spraying–drying technique was used to coat the fluidized granules. The surface polarity, surface structure, and hygroscopic water absorption rate of the coated AN particles were studied by surface energy measurement, SEM, and controlled moisture storage experiments. It was shown that the coated AN particles possessed low surface polarity and low rates of hygroscopic water absorption.

Gravimetric analyses of AN coated with eight different waterproofing materials in comparison to uncoated AN were conducted at different relative humidity and exposure durations [35]. The results indicated that mineral jelly is a promising waterproofing material for AN among the materials tested, which included calcium stearate, dioctyl phthalate, kaoline, diethyl phthalate, dinitrotoluene, shellac varnish, and beeswax. Coated AN was characterized using differential thermal analysis (DTA) and XRD.

Ammonium nitrate has been modified by evaporative recrystallization from a solution containing hexadecyl trimethyl ammonium bromide and sodium dodecyl sulfate surfactants [36]. The physical property of the modified compound was

investigated by SEM, DSC, specific surface area, and particle size measurements. The results showed that compared with common AN, the modified AN had an irregular crystal shape, greater specific surface area, better particle size distribution, lower heat of crystal pattern transition, and higher phase-change transition temperature. This indicated that the modified AN had a mesoporous structure with good self-sensitizable, anti-hygroscopic, and anti-caking performance as an oxidizer in industrial ANFO explosive.

Ammonium nitrate was coated by precipitation polymerization of styrene in chloroform solution [37], and the effects of the polymerization process conditions on the hygroscopicity of the coated AN were investigated. The results showed that the hygroscopicity of the coated AN decreased at first and then increased with an increase of the styrene concentration and polymerization temperature. The minimum hygroscopicity was attained with a styrene concentration of 4% and a polymerization temperature of 333 K (60 °C). The hygroscopicity rate of water absorption was reduced by 88.8% in comparison with uncoated AN. The hygroscopicity of the coated AN was also affected by the particle size of the uncoated AN. Within the scope of the experiments, the hygroscopicity of the coated AN was lower the smaller the particle size.

In order to strengthen the bond strength between PSAN and a binder, a silane bonding agent that can form hydrogen bonds with PSAN was selected to coat the PSAN particles [38]. Modified PSAN was characterized by SEM and XPS. It was shown that the surface morphology of coated PSAN changed greatly, and the coating caused the contact angles of nitroglycerine (NG) and diethylene glycol dinitrate (DEGDN) on the surface of modified PSAN to be reduced by about 56 and 63%, respectively. At the same time, the rate of moisture absorption of modified PSAN was reduced by about 15%. Processing the modified PSAN into PSAN/3,3-bis (azidomethyl)oxetane-tetrahydrofuran copolymer (BAMO-THF) propellants, the test results showed that tensile strength of the propellants was improved by about 65%, and the amount of dewetting was reduced by about 20%.

A supercritical fluid solvent/anti-solvent process was used to coat AN with nitrocellulose, using acetone as co-solvent and supercritical CO₂ as anti-solvent [39]. The effect of temperature, pressure, and speed of precipitation on the quality of the coating was investigated using SEM and moisture absorption measurements. The results showed that the temperature in the process is a key factor affecting the coating quality. The optimum conditions of the process were temperature, 304 K (31 °C); pressure, 10 MPa; and CO₂ release rate, 10–15 kg/h. The mass fraction of nitrocellulose in the finished product was about 1%. Such coatings reduced the hygroscopicity of AN remarkably. The hygroscopicity, fluidity, and dispersibility properties of coated AN were greatly improved.

To improve the mechanical properties of propellants containing PSAN, ethylenediamine (EDA) was reacted with the surface of PSAN particles to prepare reactively-coated PSAN [40]. The extent of the chemical reaction between EDA and AN was confirmed by Fourier-transform infrared spectroscopy (FTIR), and the coating effect was

characterized by hygroscopicity and contact angle measurements. The results showed that the surface polarity of coated PSAN particles decreased and that the hygroscopicity was much less than that of untreated PSAN. When coated PSAN was used for making PSAN/BAMO-THF propellants, the best improvements of the mechanical properties of the propellants were with PSAN coated with 0.2 mass-% EDA. The maximum stress increased by about 46%, and the elongation increased by about 83%. Similar coatings were achieved using diethylamine and triethylamine [41].

For improving the hygroscopicity and surface polarity of PSAN, EDA, diethylamine, and triethylamine were selected to react with the surface of PSAN particles to prepare reactively-coated PSAN. The coating effects were characterized by measuring the rate of moisture absorption, contact angles, and propellant tensile strength. It was shown that the hygroscopicity and surface polarity of PSAN reactively coated by diethylamine gave the best results compared with the others. The rate of moisture absorption in 8 h declined by 60.5 and 63.6% in the atmospheres of 75.3 and 92.5% relative humidity, respectively. The polar component of surface free energy declined by about 87%, and the non-polar component increased by about 145%. Using reactively-coated PSAN powders in PSAN/BAMO-THF propellants, it was found that the propellants using the PSAN coated by EDA had the best mechanical properties, and the maximum stress (σ_m) could be obtained at 0.2% coating mass of EDA. The chemical reactions between amines and AN were confirmed by surface FTIR

AN can be coated by dispersing AN particles in a non-polar solvent (petroleum ether or cyclohexane) at a mass ratio of 1:(2–20) at 293–333 K (20–60 °C); dissolving a coating agent in a polar solvent (ethyl acetate, acetone, methanol, ethanol, or tetrahydrofuran) at a mass ratio of 1:(100–5000); dripping the coating-agent solution into the AN solution at a coating agent/AN weight ratio of (0.0001–0.1):1; stirring; allowing reaction for several hours; and then removing the solvent and vacuum drying at 333 K (60 °C) to obtain coated AN [42]. The coating agent can be an organic primary amine, secondary amine, or tertiary amine, such as ethylenediamine, diethylene triamine, triethylene tetramine, triethylamine, diethylamine, hexamethylenediamine, or octadecylamine. The coating method is also suitable for coating ammonium perchlorate or ammonium dinitramide particles. The coated AN has reduced moisture absorption and lowered surface polarity, resulting in improved mechanical properties of propellants produced with it.

The fluidized bed technology allows the production of composite particles consisting of layers of different energetic materials. Spherical AN particles could be coated with ultraviolet (UV)-curing polymers (urethane oligomer [meth]acrylate monomer blend), which lead to mechanically stable core-shell structures [43]. The mean particle-crushing strength could be increased from 21.9 to 31.9 N/mm² by adding only 3% of the coating material. Figure 1 shows uncoated and coated AN particles at three different magnifications.

Polyvinyl acetate (PVAC), sliced paraffin (wax), and polyethylene glycol (PEG) were evaluated as coating materials using the liquid coating technology [44]. The

Figure 1: Coated and uncoated spherical ammonium nitrate. (Reproduced from [43] with permission from Fraunhofer Institute of Chemical Technology.)

coated samples were characterized by SEM and DSC. The experimental results showed that the modification effects of PVAC and wax were good, but PEG did not coat very well. The appearance of modified AN presented spherical particles, but free-flowing properties were better. The moisture absorption rate decreased by 30.6 and 23.3% respectively, after 24 h at ambient temperature (303 K [30 °C]) and in a relative humidity of 75%.

The surface of AN was modified by heating, melting, and applying modified paraffin as coating material [45]. The structure and surface properties of coated AN were characterized by infrared (IR), SEM, contact angle, and hygroscopicity measurements. Results showed that the gap of AN coated with modified paraffin was significantly reduced. When the mass fraction of modified paraffin was 0.5%, the film covered most of the surface. When the mass fraction of modified paraffin was 2.5%, the film was uniform and perfect, the water-wetting surface tension decreased from 9.04×10^{-2} to 1.883×10^{-2} N/m, and the amount of moisture absorption after 24 h decreased by 88%. However, what the researchers did not test was the detonability, since the composition of the paraffin-coated AN would now be similar to that of ANFO.

A phase-separation physical coating method was used for coating AN particles with polystyrene [46]. The effects of the volume ratio of toluene and *n*-hexane, the mass ratio of polystyrene and AN, the ratio of AN and mixed solvent, and the precipitating-agent addition rate on the coating of AN particles were optimized. The results showed that the optimum process conditions of polystyrene-coated AN were a 1 : 3 volume ratio of toluene and *n*-hexane, a 3.5 mL/g ratio of mixed solvent and AN, room

temperature, and 6 s/drop for the addition rate of the precipitating agent. When the 60-mesh AN was coated with polystyrene and the mass ratio of polystyrene and ammonium nitrate was 1.54%, the reduction in the moisture absorption rate was 75%.

A phase-separation method for the physical and chemical coating of AN with shellac used *n*-butyl alcohol as the solvent and *n*-hexane as the precipitant [47]. The coating was characterized by measuring the moisture-absorption rate of coated AN. The results showed that the preferred process conditions for making shellac-coated AN were a 1:3 volume ratio of *n*-butyl alcohol to *n*-hexane, 5.0 mL/g for the mass ratio of mixed solvent and AN, and 6 s/drop for the precipitation agent addition rate. The absorbed shellac amount was inversely proportional to the particle size. The moisture absorption was reduced by 55% for shellac-coated ammonium nitrate under the preferred coating conditions.

An excellent review of the available information on various coating methods for the surface modification of AN for reducing its hygroscopicity summarizes the recent advances and issues involved in AN surface modification by physical, chemical, and encapsulation coating methods [48]. Coating materials, process conditions, and the hygroscopicity test conditions are extensively discussed along with summaries of the advantages and disadvantages of each coating method. The findings indicated that the investigation and development of anti-hygroscopicity coatings of AN may require further research in order to further reduce the hygroscopicity. In physical coating methods, the hydrophilic tails of the surfactant materials attach to the polar surface of AN particles and make a hydrophobic uniform membrane on the surface. The success of this process mainly depends on the solubility of the surfactant and the insolubility of AN, as well as on the suspension of particles in aqueous solution.

2.2.3.1 Anti-Caking Agents for Ammonium Nitrate

Historically, attempts to reduce the caking tendency of AN have depended on the following:

1. keeping the AN dry, either by preparing it almost completely free from moisture and protecting the granules with a coating of organic waterproofing agent by adding a desiccating agent, e.g., anhydrous copper sulfate, or
2. adding a coating of a finely powdered, insoluble material of good covering power to the salt in order to separate the crystals from one another or to absorb the liquid phase present in the moist salt, or
3. preparing the granules so they are as uniform in size as possible so that crystallization on standing, due to the increased solubility of finely divided particles as compared with coarse granules, is avoided, or
4. preparing the granules as uniform spherical particles so that the number and area of contacts between granules are minimized; any saturated solution inclusions may be distributed over the large surface areas of the particles and held by surface tension forces in the interstices, or

5. adding crystal habit modifying dyes, which when dissolved in the saturated saline solutions in small concentration (about 0.10%) can bring about very marked changes on the habit of crystallization of these salts [49, 50]. Ammonium nitrate IV, the modification of the salt stable between 305.4 and 255 K (32.3 and -18°C), normally crystallizes as rhombic bipyramids elongated on (001) faces, with the facial development being almost entirely along (110) faces. Dyes capable of modifying the crystal habit of AN, e.g., acid magenta (sodium or ammonium salts of di-sulfonic and tri-sulfonic acids of pararosaniline) eliminated the elongation on (001), and in place of the normal facial development, a platy habit on (010) with a dendritic growth mechanism was produced, but the crystal habit of AN phase III stable above 305 K (32°C) was not greatly affected by acid magenta.

The most widely used anti-caking agent for AN is clay or kaolin [51] in different forms, mostly mineral grade from the nearest clay pit, and is often poorly defined. Diatomaceous earth has been tested as an anti-caking coating. Any of these may be acceptable for fertilizer-grade AN, but they have caused rejections for AN that was to be used in propellants or blasting agents.

Claims that anti-caking agents will not only prevent caking but at the same time also prevent phase transitions have been made, but XRD will usually prove otherwise. Anti-caking agents with this property include fumed silica with a large surface area $250\text{--}350\text{ m}^2/\text{g}$ and a pore size of $100\text{--}250\text{ \AA}$ that also absorbs some of the moisture [52].

Surfactants such as quaternary salts of alkylsulfonic acids have been added to change the crystal habits of AN and prevent caking. Stearyl amine is an anti-caking agent for AN and can be coated on the prills or crystals [53]. The combination of stearyl amine with some fine powders and coating agents can effectively prevent the caking of AN.

Prilled fertilizer-grade AN is often coated with limestone or dolomite powder as an anti-caking agent. The coating affects the thermal decomposition of coated prills [54]. Chemical interactions occur during thermal decomposition of AN prills coated with limestone or dolomite powder.

Quite often, additives that will prevent or shift the $\text{IV} \leftrightarrow \text{III}$ phase change will also prevent caking. One of these additives is zinc oxide or the zinc tetrammino nitrate formed therefrom in the molten AN.

2.2.3.2 Porous Ammonium Nitrate

For certain applications, mostly explosives and blasting agents, it is desirable to use AN that has a controlled porosity. In the case of ANFO, this would allow the fuel oil to be absorbed into the granules, and it would be held by capillary forces instead of seeping out and segregating in a tall column of explosive in a borehole.

However, porous AN (even before the fuel oil is added) may have a higher cap sensitivity than nonporous, granular AN. It was even proposed to increase the porosity of AN to a point that it would become “self-sensitized,” i.e., cap sensitive without a fuel and without a booster (Section 2.8.3). Porous AN is not typically used in rocket propellants, although it may help to obtain higher burning rates but at the expense of increased sensitivity and reduced propellant density.

Porous AN is also sometimes called “expanded AN” or “foamed AN.” Expanded AN in fine crystalline form having a specific surface area greater than $500\text{ cm}^2/\text{g}$ can be prepared by vacuum flash evaporation or crystallization from an aqueous solution in the presence of a surfactant such as laurylamine acetate [55–57].

In addition to purity and crystal structure of the material, physical properties of porous AN must be characterized by measuring the void volume, average pore size, pore size distribution, active surface area, and crush strength [58].

The wettability and porosity of AN prills is one of the primary factors determining the physical stability and detonation behavior of ANFO and how AN bonds to its binder in solid propellants. The wettabilities of various types of AN prills were compared using capillary penetration measurements [59]. Additional SEM imagery and thermogravimetric analysis (TGA) tests were performed to explain the observed differences in wettability. The wettability of AN was found to be affected by several factors, including surface tension, viscosity, density, and purity of the liquid used, as well as by surface composition, porosity, bulk density, particle size, moisture content, and thermal history of the AN samples.

In order to study the self-sensitizing structural characteristics of AN used for industrial blasting agents, the pore-structure characteristics (such as porosity, pore diameter, specific surface area, and pore distribution) and particle shape of three types of AN prills were investigated using the mercury penetration method and SEM [60]. Results showed that there are numerous pores, and the pore quantity whose size is within the effective hot-spots range is much higher in expanded AN samples, where its self-sensitizing characteristic due to adiabatic compression of pores (low-velocity detonation) is obvious. In another expanded AN sample, there were also many pores, but the pore size was much smaller and the pore size distribution was narrow. A third expanded AN sample was similar to common commercial AN, i.e., the porosity and surface area were much lower, and the pore fraction within the effective hot-spots range was less.

2.3 Physical Properties of Ammonium Nitrate

The physical properties of AN have been thoroughly investigated, in particular physical properties relating to the phase changes that AN undergoes with changes in temperature. Ammonium nitrate is hygroscopic, so it is important to measure properties

on absolutely dry samples of the material and to work in a dry box or even under dry nitrogen. Properties of AN are summarized in [61–63].

The molecular mass of AN is 80.043 g/mol (IUPAC 1962 atomic mass $^{12}\text{C} = 12.000$), which corresponds to 12.493 mol/kg.

2.3.1 Melting Point and Phase Changes of Ammonium Nitrate

2.3.1.1 Melting Point of Pure Ammonium Nitrate

Literature sources give the melting point of AN as 442.75 K (169.6 °C or 337.3 °F) Once it melts, AN begins to decompose under formation of nitrous oxide (Section 2.4.6.1).

2.3.1.2 Polymorphism and Solid State Phase Changes of Pure Ammonium Nitrate

Although the fact that AN shows polymorphism and undergoes multiple phase changes has been known for a very long time [64], the study of its phase changes and how to modify or avoid them continues to this date. Hundreds of publications on this subject can be found in the literature, and it is not our intent to collect them all for this book. Uncontrolled phase changes adversely affect our ability to use AN as a rocket propellant, so we must understand it before we select it as a propellant ingredient. Ammonium nitrate exists in five different phases, and each has a different crystal structure and density. The phases are often described by lowercase Greek letters or Roman numerals, but the sequence of numbering of the two numbering systems runs in opposite directions, shown here along with the phase transition temperature:

	–18 °C		+32.1 °C		84.2 °C		125.2 °C		169.9 °C	
Tetragonal	↔	Orthorhombic	↔	Orthorhombic	↔	Tetragonal	↔	Cubic	↔	Liquid
α		β		γ		δ		ϵ		
V		IV		III		II		I		

The temperatures at which the phase transformations take place depend somewhat on the method used to measure them. Thus, dilatometric methods, XRD, and DTA may report slightly different transition temperatures. Although there are two tetragonal and two orthorhombic structures, the crystal lattice parameters are still different. Phase changes of AN are one of the reasons that AN has not been used more widely in rocket propellants and gas generants. Swelling and shrinking as a consequence of repeated phase changes cause debonding of oxidizer particles from the binder or delaminating of a solid propellant grain from the casing, resulting in uncontrollable burning behavior that often leads to explosions. Additional information on density changes of AN as the result of phase changes is summarized in Section 2.3.11.1. A significant amount of effort has been devoted to finding phase stabilizers for AN that will prevent phase changes or at least shift the temperature at which they occur (Section 2.4.1). The crystal structures of the various phases of AN and its solid solution phases with poten-

tial stabilizers are discussed in Section 2.3.11.6. Methods used for the study of phase changes are summarized in Section 2.3.11.3.

The phase changes in high-purity AN were studied by a DTA apparatus designed for constant heating and cooling rates and continuous repeated cycling for ~3-g samples [65]. Based on an analysis of DTA and XRD data, a very consistent phase-change behavior was observed. Phase IV $\rightarrow$ III transformation on heating in the range of 316–324 K (43–51 °C) and phase II $\rightarrow$ IV transformation on cooling in the range of 322–326 K (49–53 °C) were demonstrated repeatedly. The III $\rightarrow$ II transition at about 359 K (86 °C) was seen even with repeated temperature cycling. This repeatable behavior was not consistently seen by other investigators using different techniques, and it is believed that it was due to the high-purity material and constant heating and cooling rates used in this particular study.

Pure AN has five different solid phases and undergoes four different solid–solid phase transitions before melting. An excellent summary of the phase transitions of AN and potassium nitrate (KN) was published by the National Bureau of Standards (now the National Institute of Standards and Technology) [66]. In that book, the chapter on AN in pages 24–30 contains a detailed description of AN phase changes, supported by 77 mostly historical literature references. Another good summary was published by Chien [67, 68] as part of a study of the AN/KN binary system (Section 2.3.11.6).

Differential scanning calorimetry was used alone and in conjunction with Raman spectrophotometry for simultaneous calorimetric and spectral measurements to study the solid state phase transitions of ammonium nitrate between 223 and 373 K (–50 and 100 °C) [69]. On heating, two transition paths were observed between 233 and 273 K (–40 and 0 °C): one showing two separate peaks on DSC and the other showing only a single peak. The latter path became dominant when samples were thermally cycled. There was little hysteresis when going through several cycles. The double transition was followed by transition IV $\rightarrow$ II at 324 K (51 °C) and the single transition by transitions IV $\rightarrow$ III $\rightarrow$ II at higher temperatures at about 323 and 360 K (50 and 87 °C). Raman spectra showed that there were two phases present between the two DSC peaks at low temperature. The first endotherm peak was attributed to a transition from the phase designated as V to phase IV, and the second peak to a transition from V to IV. The single peak below 273 K (0 °C) was due to the transition V $\rightarrow$ IV. In continuation of this work, it was noted that the solid state phase transition path of AN is influenced by the crystallization history [70]. Slow crystallization from water gave ideal crystals, which behaved differently from crystals prepared by rapid crystallization from the melt.

The effect (if any) of crystallization methods on the IV $\leftrightarrow$ III transition of AN has not been unanimously accepted in the crystallographic community. To clarify this problem, AN was crystallized in three different ways, recrystallization, evaporative crystallization, and melt crystallization, and was characterized by DTA, XRD, and SEM [71]. When the samples were crystallized from saturated aqueous solution, ideal crystals were formed, which behaved differently from the crystals formed by the other methods. The DTA examination of the crystals showed that the crystals have differ-

ent phase-transition behavior. The moisture uptake of the samples was influenced by the mode of crystallization. The samples were further analyzed by XRD and SEM. The results showed that parameters such as thermal history, number of previous transformations, and moisture content have a very negligible influence on the IV $\leftrightarrow$ III transition of AN compared to the method of crystallization.

In a comparison of DSC results with an identical sample of AN performed in four different laboratories, the agreement between phase transition temperatures and enthalpies of transition for four phase transitions was remarkably close [72]. See also [73–77].

Pressure Dependence of Solid State Phase Changes of Pure Ammonium Nitrate

Phase diagrams between 273 and 473 K at pressures between 0.98 bar (1 kg/cm^2) and 11.77 kbar (12000 kg/cm^2) showed a previously unknown modification of AN [78, 79]. Some second-order phase transitions do not occur under conditions of hydrostatic compression but can take place when a shear stress is applied in addition to isostatic pressure. A diamond anvil cell used without a gasket around the sample is an excellent device for studying shear stress-induced transitions. Under hydrostatic conditions, AN does not undergo a phase transition at pressures up to 5.0 GPa. However, under shear stress conditions, a shear-induced transition was observed at 2.94 GPa [80]. Under shear stress, AN showed an upward break in the shear stress vs. pressure curve at 29.4 kbar, indicating a shear-induced transition. This transition was also observed at 3.0 GPa using IR spectroscopy of a thick film under non-hydrostatic conditions in a non-gasketed diamond-anvil cell [81]. Failure to observe this shear-induced transition in very thin films of sample is probably due to the very small amount of sample in the film actually experiencing pressures above 30 kbar.

A new modification VI was detected during a study of the phase transformations of AN by DTA at high pressures at 0–35 kbar and 223–623 K [82]. The univariant lines of the I $\rightarrow$ VI, IV $\rightarrow$ VI and I $\rightarrow$ IV transitions were found to intersect at a triple point near 19.5 kbar and 529 K.

The temperature range of stability of three modifications used for a pressure-effect study was V = α ($T < 255 \text{ K}$), IV = β (255–305.1 K), and III = γ (305.1–357.2 K). The average value for the increase in the volume expansion for the IV $\rightarrow$ III transition at atmospheric pressure was found to be 6.5%. In studying the effect of pressure on the polymorphic transformations of AN between stable modifications and the compressibility of different modifications of AN under isothermal conditions, it was found that the temperature for the start of the IV $\rightarrow$ III transition was shifted from 305 K at 101 kPa to 316 K at a pressure of 392.24 bar = 400 kg/cm^2 [83]. It was also found at pressures between 100 and 6000 kg/cm^2 that modification IV, which is stable between 255.1 and 305.2 K (–18 and 32.1 °C), does not show relaxation under pressure because of a very small change in molar volume. The modification III, which is stable from 305.2 to 357.3 K (32.1 to 84.2 °C), possesses the largest molar volume of all known crystal modifications of this salt and easily transforms to modification IV at 323 K [84].

The solid-state transition mechanisms of ammonium nitrate IV, III, and II were studied by measuring samples simultaneously using Raman spectrometry and DSC [85]. The spectral data of the transitions were collected simultaneously with the calorimetric data in the temperature-scanning mode of the calorimeter and then isothermally between transitions. The phase transition from phase IV to phase III occurred through an intermediate phase II*, whose lifetime was 7 min maximum when the onset temperature of the reaction was close to the phase-transition IV → II onset temperature. It was concluded that there is always an intermediate phase II* between IV and III. Simultaneous Raman measurements were shown to be an effective tool for interpreting complex DSC curves.

Bulk sound speed measurements, isothermal volume compression/XRD experiments, and shock loading experiments (maximum pressure ~20 GPa) were performed for high initial density ($\geq 94\%$ theoretical density) AN and AP [86]. The experimental data, and the full-density Hugoniot calculated from that data, suggested the presence of low-pressure shock-induced phase transitions in both AN and AP. The AN phase change occurs at a shock pressure of less than 3.5 GPa, but the associated volume change is relatively large, indicating the presence of a previously unidentified high-pressure, high-density phase.

Besides the known six phases at atmospheric pressure, there are five phases at high pressures. Phase VI occurs at temperatures above 442 K and pressures greater than 0.9 GPa. Phase VIII, which is stable between 0.45 and 2.7 GPa, transforms into phase IX above 2.7 GPa and room temperature. However, the crystallographic information of phases VI, VIII, and IX is unclear. A shock-induced phase change at 3.5 GPa has been observed, but the structure is uncertain. A metastable isostructural transition (IV–IV') at about 20 GPa under non-hydrostatic compression was suggested, but there is no phase transition until 35 GPa under hydrostatic compression.

The influence of pressure on phase transitions, melting, and thermal decomposition characteristics of pure AN was measured using a pressure-differential scanning calorimeter under ambient conditions and up to a maximum inert pressure of 68.03 atm [87]. The temperatures of the three phase transitions occurring above room temperature were distinctly shifted with increasing pressure, went through a maximum around 40 atm, and then dropped again (Table 2).

The shape of the DSC thermogram curves of AN changed with increasing pressure (Figure 2a–d). The most pronounced change at the highest pressure tested is the appearance of a sharp exothermic decomposition peak at 586 K (313 °C) at 68 atm (Figure 2d). Note that the four thermograms have different ordinate scale expansions.

Using a combination of XRD and neutron diffraction techniques augmented by vibrational spectroscopy, structural information of fully deuterated d-AN was obtained at pressures up to ~8 GPa [88, 89]. High-pressure measurements have been conducted on ammonium nitrate up to 7.85 GPa, showing no phase transitions. An equation of state has been determined over this pressure range. Under hydrostatic conditions, AN remained in the ambient phase IV at pressures up to 7.0 GPa. Significant changes in the

Table 2: Effect of pressure on phase transition, melting, and decomposition temperature of AN.

Sample no.	Pressure atm	DSC peak temperature (°C) for

Data source: [87]

extent of hydrogen bonding between the ammonium and nitrate ions were observed over this pressure range. In a sequence of powder patterns obtained for fully deuterated AN with increasing pressure up to 7.85 GPa, all of the patterns could be indexed to the orthorhombic unit cell (space group *Pmmn*) of phase IV. Full-profile Rietveld refinements of the neutron powder diffraction patterns enabled refinement of the crystal structures. Over this relatively limited pressure range, there were no changes in the primary bond lengths for the ND_4^+ and NO_3^- ions. Instead, the effect of pressure was to modify the hydrogen bonding interactions. The O1...D2 contact distance is reduced from 2.256(25) Å at ambient pressure to 1.888(9) Å at 7.03 GPa. This contact has a significant component along the *b*-axis and so explains why this axis is the most compressible over this pressure range.

Ammonium nitrate phase changes have been studied under both hydrostatic and non-hydrostatic conditions using diamond anvil cells combined with micro-Raman spectroscopy and synchrotron XRD [90]. The refined-powder X-ray data indicated that under hydrostatic conditions, AN-IV (orthorhombic, *Pmmn*) is stable to above 40 GPa. The structures of phase IV and IV' were similar, with a subtle difference in the hydrogen-bonding network; that is, a noticeably shorter N1...O1 distance was seen in phase IV'. On the basis of this comparison, it was postulated that a chemical reaction or phase transition may occur in AN under dynamic pressure conditions at 22 GPa.

The pressure–temperature (P-T) phase diagram of AN has been determined using synchrotron XRD and Raman spectroscopy measurements [91]. Phase boundaries were established by characterizing phase transitions to the high-temperature polymorphs during multiple P-T measurements using both XRD and Raman spectroscopy measurements. At room temperature, the ambient pressure orthorhombic (*Pmmn*) AN-IV phase was stable up to 45 GPa, and no phase transitions were observed. AN-IV phase was also observed to be stable in a large P-T phase space. The phase boundaries were steep, with a small phase stability regime for high-temperature phases. A pressure–volume–temperature (P-V-T) equation of state was obtained by simulta-

Figure 2: DSC thermograms of AN at increasing pressure. (a) 1 atm, (b) 27.2 atm, (c) 40.8 atm, (d) 68 atm (Reproduced and modified from [87] with permission from © Indian Chemical Society 2003; Permission granted 14-Apr-2021.)

neously fitting the P-V isotherms at 298, 325, 446, and 467 K; thermal expansion data at 1 bar; and volumes from P-T ramping experiments. Anomalous thermal expansion behavior of AN was observed at high pressure with a modest negative thermal expansion in the 3–11 GPa range for temperatures up to 467 K, probably due to vibrational anharmonicity.

An investigation of the phase stability of AN at high pressures and temperatures, using diamond anvil cells and micro-Raman spectroscopy, confirmed the existence of a phase IV-to-IV' transition above 17 GPa and provided new constraints for the melting and phase diagram of AN up to 40 GPa and 673 K (400 °C) [92, 93]. Pure AN decomposed at the onset of melting of phase I, whereas phase IV' showed an unusual turnover of the decomposition temperature well below the melting. There were strong chemical effects on the phase transitions and chemical decomposition of AN.

Effect of Moisture and Humidity on Solid State Phase Changes of Pure Ammonium Nitrate

Phase changes in AN are greatly accelerated by the presence of traces of moisture. For all practical applications, it is virtually impossible to eliminate moisture during propellant processing, transportation, and storage. AN is very hygroscopic, and other than applying vapor barrier coatings, there are few things one can do to AN to make it less hygroscopic [94].

Perfectly dry phase IV AN stabilized with 9% KN was heated from room temperature to 333 K for 300 h, with samples withdrawn periodically and analyzed by XRD. The perfectly dry samples did not show any phase changes, but a sample that was allowed to absorb 0.1% moisture at 298 K underwent phase change under the same conditions [95].

Other sources [96] have reported that the IV → III transformation is very slow in perfectly dry samples, requiring months at 306 K (33 °C) and 0.5 h at 313 K (40 °C). However, opinions differ on the critical moisture content that accelerates or retards the transition. Others state that in a perfectly dry sample transitioned at 328 K (55 °C) (mainly IV + III) but with more than about 0.1% moisture present, a constant transition temperature of 308 K (35 °C) was observed. The III → II transition is not affected by the presence of water [97].

The IV → III phase transition takes place in saturated-solution aqueous slurries of AN crystals [98]. There have been many previous studies of the IV → III phase transition, and water is known to play a mechanistic role. The effect of other solvents and additives on the transition kinetics of single crystals was examined, and these data were combined with structural information to examine the overall mechanism of the transition [99]. The data were consistent with a theory about solvent mediation in which the interface between phases is a microscopic layer of AN solution.

AN aerosols may form in highly polluted atmospheres. Solid AN exists in five stable polymorphic forms (designated as phases I, II, III, IV, and V) below its melting point at around 443 K (170 °C). Phase IV is stable in a temperature range of 256 to ~305 K

(-17 to ~32°C). The IV ↔ III phase transition of NH_4NO_3 and the effects of relative humidity on the transition path and the transition temperatures were examined using *in situ* microscopic FTIR spectroscopy [100]. Two kinds of NH_4NO_3 samples – powder produced from grinding of commercially produced chemicals and single particles obtained by efflorescence of droplets on polytetrafluoroethylene filters – were studied. The powder samples exhibited the IV ↔ III phase transition, and the transition temperature depended on the relative humidity, whereas the single-particle samples exhibited only the IV ↔ II transition at about 325 K (52°C) (forward) and 321 K (48°C) (reverse), bypassing phase III, with transition temperatures independent of the relative humidity. However, grinding of the particles produced through efflorescence resulted in the IV ↔ III transitions becoming visible. Differences in crystal structure and moisture content may explain the distinct phase-transition behaviors of the two types of samples. These results suggest that solid and pure NH_4NO_3 aerosol particles are stable in phase IV under ambient conditions.

Effect of Grain Size on Solid State Phase Changes of Pure Ammonium Nitrate

The reproducibility of the DTA curves of AN as a function of its grain size and the surrounding atmosphere during the measurements was studied, and the temperatures and the areas of the peaks assigned to the modification transitions IV → III (peak 1), III → II (peak 2) and II → I (peak 3) were evaluated [101]. It was found that for some unground samples, the area of peak 2 decreased markedly. In an atmosphere of moist air, the temperature of peak 1 was lowered. The temperatures of lumpy and loose samples did not differ appreciably.

2.3.1.3 Melting Point of Binary Ammonium Nitrate Systems

Many different methods can be used to construct phase diagrams of binary systems. For example, the T-X phase diagram is based on the van't Hoff equation, and the H-X phase diagram is based on the mixture law. The construction of an H-X phase diagram is quicker and simpler than that of a T-X phase diagram. However, an H-X phase diagram cannot be used to determine the composition of a mixture or its melting temperature. A T-X phase diagram describes the relationship between the composition and the melting temperature.

Melting Point of Ammonium Nitrate/Water System

The eutectic point in the AN/water system is at 58 mass-% (23.7 mol-%) AN, with a melting point of 256 K (-17°C). These data are very similar to those for ADN.

Melting Points of Binary Ammonium Nitrate Systems with Other Nitrates

Numerous alkali metal nitrates and other metal nitrates have been studied as additives to AN in order to shift or totally avoid some of the troublesome phase changes that make it difficult to use AN as a rocket propellant or gas generant in airbag inflators (Section 2.11). Nitrates evaluated include potassium nitrate and magnesium nitrate.

Potassium nitrate would be acceptable as a stabilizer because it is an oxidizer in its own right and would not detract too much from the value of AN as an oxidizer in rocket propellants or gas generants. Magnesium nitrate is not preferred because it is very hygroscopic.

The phase diagram of the system $\text{NH}_4\text{NO}_3/\text{KNO}_3$ is extremely complex and has been measured repeatedly, not always with identical results. The following pages provide a comparison of AN/KN phase diagrams from different sources. These diagrams do not all use the same nomenclature for the various phases. Some of the diagrams extend over the entire range of AN/KN compositions, whereas others examine only the AN-rich side of the system. This is why so many different diagrams are shown in the following pages and why they are so difficult to compare. One of the earliest phase diagrams of this system is shown in Figure 3; [102].

The transition curve $\text{II}'\text{A} \rightarrow \text{IVA}$ in the system $(\text{NH}_4)_x\text{K}_{1-x}\text{NO}_3$ was measured in the range $1 > x > 0.75$ [103]. The suffix A or K is used to differentiate phases, which otherwise have the same denomination by their crystallographic properties (e.g., II_A = tetrago-

Figure 3: Phase diagram of the system $\text{NH}_4\text{NO}_3/\text{KNO}_3$. (Republished and modified from [102], with permission from © 1932 John Wiley & Sons; permission conveyed through RightsLink.)

nal and II_K = rhombic). A single phase II' of AN-rich mixed crystals was observed in the completely miscible range from $x = 1$ to 0.918 (where x is the molar fraction of AN). From $x = 0.913$ to 0.750, two phases occurred simultaneously: II'_A as an ammonium-rich phase and II_K as an undercooled potassium-rich phase. The stable phase at room temperature III_A formed readily on cooling. The complete miscibility range of phase III_A extended over the entire range mentioned above. It is assumed that homogenization of the formerly phase-separated crystals takes place by ion diffusion in the solid state. In the Figure 4 phase diagram, the striated areas represent the occurrence of each phase in the metastable phase diagram. The names of the phases are given next to the three legend boxes at the top, showing the different fill patterns.

Figure 4: Phase diagram of the AN-rich side of the system $(\text{NH}_4)_x\text{K}_{1-x}\text{NO}_3$. (Reproduced and modified from [103], with permission from Schweizerische Geologische Gesellschaft 17-Jul-2021.)

The melting point vs. composition curve (Figure 2 in Leone [103], but not shown here) has an inflection and slope change at $x = 0.918$, dividing the graph into two zones: the zone of complete miscibility for phase II'_A up to $X = 1$ and the zone of partial miscibility, where II'_A coexists with II_K . In the range $0.75 < x < 0.918$, two types of crystals of modification III_A , having different compositions, will form. Phase changes are accompanied by considerable change in the refractive index and birefringence.

The AN/KN phase diagram in Figure 5 was constructed from visual observations with a hot-stage microscope [104]. Only a portion of the binary-phase diagram for the system AN/KN with up to 30 mass-% potassium nitrate has been determined from

218 to 458 K (−55 to +185 °C). The AN/KN mixtures were prepared by dissolving KN in molten AN and quick-freezing the clear melt by pouring it onto a Teflon sheet. The KN concentration was limited to 30 mass-% KN because the temperature required to dissolve KN, which increases rapidly at this concentration, has reached the point at which significant AN decomposition begins to take place.

Figure 5: Phase diagram of the AN/KN binary system. (Republished and modified from [104], with permission of © 1981 Wiley VCH; permission conveyed through Copyright Clearance Center, Inc.)

The lengths of the vertical data-point bars in Figure 5 represent the temperature difference between an observation in which the lower-temperature phase was clearly stable and an observation in which the higher-temperature phase was clearly stable.

Single-ended data-point bars indicate that the transformation was observed in only one direction. Phase boundaries between stable phases are indicated by solid lines when their positions are known and by dotted lines when their positions could be inferred only by extrapolation. Dashed lines indicate boundaries between metastable phases.

A very detailed AN/KN phase diagram over the entire range of compositions was obtained by using DSC and *in situ* high-temperature XRD [67, 68] (Figure 6). That paper also contains a thorough list of references from the literature. The enthalpies of phase transformations were measured along with the phase transformation onset and peak temperatures. The phase diagram that is the result of both DSC and XRD measurements showed that there are seven invariant equilibria: one eutectic at 16 mass-% KN and 429 K; two eutectoids, at 39 mass-% KN and 373 K and at 88 mass-% KN and 393 K; three peritectoids at 14 mass-% KN and 390 K, at 55 mass-% KN and 380 K, and at 8 mass mass-% KN and 400 K; and one congruent transition at 72 mass-% KN and 415 K.

Figure 6: Phase diagram of the AN/KN system. (Republished and modified from [68], with permission of © 2005 Springer Nature BV; permission conveyed through Copyright Clearance Center Inc.)

Earlier publications [104] reported an AN/KN phase diagram for the AN-rich end up to 30 mass-% KN. Comparison of the AN/KN phase diagram of Cady 1981 with Chien's data shows reasonable agreement in the 0–30 mass-% KN region. The phase diagram in Figure 6 supersedes older data and is quite different from AN/KN phase diagrams reported in the older literature. These older data from [105], obtained by differential thermal analysis curves, and from [106], obtained by XRD, are in poor agreement with Chien's results. See also [107] and [108]. The phase III region of AN/KN is stable be-

tween 5 and 20 mass-% KN up to ~ 373 K, which is an important finding for the intended use of phase-stabilized AN in gas generants for airbag gas generators and other applications.

See also [109–114]. Other authors have investigated the potassium-rich end of the system, but that is of less interest as a rocket propellant. A detailed summary of properties of AN/KN binary systems, as well as information on their use in fertilizer mixtures and a summary of phase diagrams published by various earlier investigators, is provided in [63].

Melting Points of Binary Ammonium Nitrate Systems with Other Non-Nitrate Salts

AN is a versatile oxidizer, and it is being tested in mixtures with many other energetic materials, preferably with materials with which it will form solid solutions and eutectic mixtures with which it will not segregate into separate phases on cooling.

AN forms a eutectic with the ethylenediammonium salt of 5-nitrotetrazole that is of interest as a melt-castable explosive [115, 116]. This eutectic mixture, which contains 87.8 mol-% of ammonium nitrate, is close to the CO_2 -balanced composition of 90 mol-% and has a relatively low melting point of 383.65 K (110.5 C), making it readily castable.

A cylindrical oxidizer grain made from a eutectic AN/AP mixture was used in an inverse hybrid rocket engine [117]. The eutectic mixture did not exhibit explosive behavior during melting or casting.

Ammonium nitrate is a cheap oxidizer. Its performance can be improved by adding perchlorates. Solid propellants containing both AN (or PSAN) and AP are called dual-oxidizer composite propellants. The AN and AP can be mixed in as individual powders, or the two salts can be co-crystallized from water and then ground to the desired particle size. AN and AP can be co-crystallized by freeze-drying [118]. AN adheres to the less-soluble AP particles during the drying process to form combined AP/AN particles. The AN content of the combined AP/AN samples dominates particle properties, including shape, hygroscopicity, thermal decomposition behavior, and ignition sensitivity.

Several propellants were formulated with the co-crystallized oxidizer and compared to conventional AP-based propellants [119]. The DTA thermogram of the co-crystallized oxidizer shows peaks that differ from those of its pure constituents:

- peak at 371 K (98 °C): beginning of the phase transition III $\rightarrow$ II of AN
- peak at 400 K (127 °C): beginning of AN phase transition II $\rightarrow$ I
- peak at 408 K (135 °C): fusion of the eutectic mixture AN/AP
- peak at 418 K (145 °C): fusion of AN
- peak at 454 K (181 °C): beginning of the first stage of exothermic decomposition
- peak at 468 K (195 °C): beginning of full exothermic decomposition

No peak was observed at 305 K (32 °C), and that is an important observation!

The phase diagrams of AN/AP and AN/sodium perchlorate were examined [120]. The melting point in the AN/AP system does not drop significantly until the AN concentration reaches 80% AN. Then the melting point drops sharply toward a eutectic containing 90% AN and melting at 419 K (146 °C). Volume 1, *Encyclopedia of Oxidizers*, chapter “Perchlorate Oxidizers” contains a melting-point diagram of the AN/AP binary system. AN/AP or AN/ NaClO_4 mixtures can be used as oxidizers for solid propellants with reduced HCl output. The system $\text{NH}_4\text{NO}_3/\text{NaClO}_4$ has a eutectic point at 10% NaClO_4 , melting at 402 K (129 °C) (Figure 7).

Figure 7: Phase diagram of the ammonium nitrate/sodium perchlorate system. (Reproduced and modified from [120].)

A phase diagram of the AN/ammonium dinitramide binary system is shown in Volume 1, *Encyclopedia of Oxidizers*, chapter “Dinitramide Oxidizers.”

2.3.1.4 Melting Point of Ternary Ammonium Nitrate Systems

Ternary systems containing AN and water and a third ingredient could be ternary mixtures containing two oxidizers and a solvent or systems containing one oxidizer, a fuel, and a solvent. The third ingredient could have a salting-out effect (as in the case of adding ethanol or methanol) or a salting-in effect (only a few additives improve the solubility of AN).

A previously undescribed modification of AN/ KN solid solution crystals was discovered when analyzing supernatant liquids and solid precipitates in two-phase AN/ $\text{KN}/\text{H}_2\text{O}$ solutions for different AN:KN ratios and at different saturation temperatures [102]. The mixed crystals have the same crystal form as that of KN when it is subjected to high pressures >115 atm.

Ternary ammonium nitrate systems have been developed both as solid and liquid oxidizers. Solid oxidizers contain two additional components as phase stabilizers or to improve other properties. Liquid oxidizers contain a solvent and one additional dissolved oxidizer to achieve low freezing points and high densities.

A continuation-in-part of an earlier patent application by Wagaman issued as U.S. patent 6299711 [121] describes AN/hydrazinium nitrate (HN)/H₂O solutions as oxidizers. It is similar to work by Mueller and Wagaman [122], except it does not use hydroxylammonium nitrate (HAN) but also includes methylhydrazinium nitrate as a potential constituent. OXSOL-3 is a mixture containing AN, HN, and water. Figure 8 is a freezing-point diagram of the AN/HN/H₂O system.

Figure 8: Freezing-point diagram of ternary AN/HN/H₂O oxidizer solutions. (Reproduced and modified from [121].)

Three different OXSOL-3 compositions were listed as examples in performance calculations (Table 3).

Table 3: Composition of OXSOL oxidizer solutions.

Composition, mass-%			Freezing point		Density
AN	HN	H ₂ O	°C	K	g/cm ³
25.0	55.0	20.0	17	290.1	1.422
41.2	43.1	32.7	19	292.1	1.441
46.4	32.7	20.8	18	291.1	1.398

Data source: [121]

These may have favorable densities, storage stabilities, and oxygen contents, but the freezing points are much higher than those of comparable ternary blends containing HAN instead of AN. Instead of dissolving AN in water, a more powerful oxidizer called PERSOL-1 can be obtained by dissolving AN in hydrogen peroxide/water mixtures [123, 124]. The freezing-point diagram of the ternary system AN/H₂O₂/H₂O is shown in Figure 9.

Figure 9: Freezing-point diagram of ternary AN/H₂O₂/H₂O oxidizer solutions. (Reproduced and modified from [124].)

One preferred composition of PERSOL-1 contains 55.6% AN, 22.2% H₂O₂, and 22.2% H₂O. This blend freezes at 276 K (+3 °C) and has a density of 1.361 g/cm³. It can serve as an oxidizer for bipropellants or hybrids. Monopropellants can be formulated by emulsifying it with hydrocarbons or by dissolving amine nitrate salts such as alkylammonium nitrate or alkanolammonium nitrates having one, two, or three carbon atoms. Adducts of AN with H₂O₂ are referred to as *peroxides* or persalts. The AN:H₂O₂ = 1:1 adduct is a solid at room temperature. Such adducts may be used as oxidizers in propellants, explosives, and pyrotechnics [125]. The ignition delays of solutions of AN or ADN in high-test peroxide with an ionic liquid fuel, 1-allyl-3-methylimidazolium dicyanamide, have been measured [126].

While it may have been the objective of some of the previous inventions to develop oxidizers that are less corrosive and less toxic than nitric acid, this does not apply to the following ternary AN solutions called ANNA (for ammonium nitrate nitric acid)

[127]. Unfortunately, the patent does not give the complete freezing-point diagram for the ternary system AN/NA/H₂O as it does for the other nitrate solutions patented by the same inventor, but it does give the density data in tabular form. ANNA-30-40 and ANNA-28-52 have favorable performance and handling properties. The solutions are stable up to about 413 K (140 °C). ANNA oxidizers were proposed as oxidizers with kerosene and water injection steam generators for powering catapults on aircraft carriers.

Ternary mixtures containing AN, water, and methanol have been considered as monopropellants (*Encyclopedia of Monopropellants*).

The phase diagram for a ternary system consisting of AN with 15 mass-% potassium nitrate (AK15)/ethylenediamine dinitrate (EDDN)/nitroguanidine (NQ) has been determined from room temperature to the melting point [128]. The ternary eutectic temperature, measured for a mixture containing 67.24 mol-% AN, 25.30 mol-% EDDN, and 7.46 mol-% NQ was found to be 372 K (98.9 °C). The binary phase diagrams for the systems AK15/EDDN, AK15/NQ, and EDDN/NQ were also determined.

Low-melting ternary blends of AN with other energetic materials are of interest as melt-castable explosives, replacing trinitrotoluene (TNT). A ternary blend containing 26.33 mass-% ethylenediammonium salt of 5-nitrotetrazole, 47.54 mass-% AN, and 26.13 mass-% EDDN has a melting point of 362.6 K (89.5 °C) [115]. The phase diagram was determined for a ternary system consisting of diethylenetriamine trinitrate (DETN)/EDDN/AN with 15 mass-% potassium nitrate (AK15). The eutectic mixture containing 40 mass-% AK15, 35 mass-% DETN, and 25 mass-% EDDN was subjected to small-scale sensitivity and performance tests [129].

Ternary systems containing AN, potassium nitrate, and sodium nitrate show similar shifts or disappearance of phase transitions [130]. A very good summary of binary and ternary molten salt systems including AN and other nitrates is given in [131].

2.3.2 Density of Ammonium Nitrate

The density of solid AN at 298 K is 1.725 g/cm³. This is the density of the IV phase, which is stable at room temperature. Ammonium nitrate exists in five different phases, and each has a different density. The specific volumes (the reciprocal densities) of the different phases of AN are illustrated in Figure 10, and calculated data are summarized in Table 4. Phase changes of AN are one of the several reasons why AN has so far not been used more widely in rocket propellants and gas generants. Swelling and shrinking as the consequence of repeated phase changes result in debonding of oxidizer particles from the binder or debonding of a solid propellant grain from the casing, resulting in uncontrollable burning behavior that often leads to explosions. A significant amount of effort has been devoted to finding phase stabilizers for AN (Section 2.4.1). Dilatometric analyses are performed to demonstrate the effectiveness of phase stabilizers and to measure the coefficients of thermal expansion between phase changes.

Figure 10: Specific volume of ammonium nitrate and phase changes

Table 4: Computed specific volumes of AN phases at different temperatures

Phase	Volume of unit cell $\times 10^{-23}$	Specific volume	Temperature	
	cm ³	cm ³ /g	°C	K
IV	15.4394	0.5792	22	295
III	32.3108	0.6080	45	315
II	16.1347	0.6070	82	355
I	8.3224	0.6262	150	423

Data source: [87]

It is clearly seen that the IV $\rightarrow$ III and II $\rightarrow$ I phase transitions result in an increase in volume, whereas the III $\rightarrow$ II transition causes only a negligible decrease. The energy release (absorption) associated with the various phase changes was also measured.

2.3.2.1 Coefficient of Thermal Expansion of Crystalline Ammonium Nitrate

The thermal expansion of AN crystals is anisotropic and depends on which phase the crystal is currently in. For instance, crystals of phase IV on heating show a slightly shrinking parameter a length and a strongly expanding parameter b length. Such behavior is difficult to explain.

2.3.2.2 Density of Binary Ammonium Nitrate Solutions

Density of Aqueous Ammonium Nitrate Solutions

If the density of AN solutions is plotted against the mass fraction of AN, the curve is slightly concave. Figure 11 shows the density of aqueous AN solutions at 323 K in comparison to densities of two other oxidizers at 298 K. The AN data were obtained at higher than room temperature because AN is less soluble in water than the other two oxidizers.

Figure 11: Density of AN solutions in comparison to other oxidizers. (Reproduced and modified from [132] with permission from Dr. Charles Kappenstein.)

The molar volumes of AN and other oxidizers were measured so that the theoretical density of oxidizer/fuel/water mixtures in monopropellants could be calculated assuming additive behavior of the molar volumes in mixtures. As a start, the reciprocal density (i.e., the specific volume) was plotted vs. the mol fraction of oxidizer, as shown in Figure 12.

Figure 12: Molar volume of AN solutions vs. mol fraction of AN in comparison to other oxidizers. (Reproduced and modified from [132] with permission from Dr. Charles Kappenstein.)

The curves in Figure 12 are straight lines such that their shape can be expressed by a simple linear function:

$$Vm = Vm_{\text{H}_2\text{O}} \times X_{\text{H}_2\text{O}} + Vm_{\text{AN}} \times X_{\text{AN}}$$

$$Vm = Vm_{\text{H}_2\text{O}} + (Vm_{\text{AN}} - Vm_{\text{H}_2\text{O}}) \times X_{\text{AN}}$$

The molar volumes of the salts were derived from the intercept of the lines. The results are summarized in Table 5.

Table 5: Extrapolated molar volume and density of pure ionic liquid oxidizers.

Compound name	Formula	Molar volume, mL/mol	Density of pure ionic liquid (no solvent), g/cm ³
Ammonium nitrate	NH ₄ NO ₃	52.00(15) ^a	1.539(5) ^a
Ammonium dinitramide	NH ₄ N(NO ₂) ₂	74.06(13)	1.675(3)
Hydroxylammonium nitrate	NH ₃ OH NO ₃	55.45(19)	1.732(6)

^aNumbers in parentheses designate the standard deviation of the last digits.

Data source: [132]

The densities of the AN-water system for water ratios R varying between 1.2 and 3.0 mol H₂O per mol of AN were measured [133]. At a given R , density ρ is a linear function of temperature, and the coefficients A and B are listed in Table 6:

$$\rho = A - B(T - 300)$$

Table 6: Empirical parameters of the least-squares-fit equations for the densities of the NH₄NO₃–H₂O system.

Mols of water R	Temperature range, K	A	$10^3 \times B$
1.2	320–345	1.39268	0.68742
1.4	315–345	1.37450	0.69481
1.6	300–345	1.35608	0.70401
2.0	300–345	1.32788	0.67619
2.5	295–345	1.30150	0.67313
1.8	300–345	1.34033	0.65436
3.0	295–345	1.27736	0.66006

Data source: [133]

The variation of ρ with R can be expressed by a polynomial equation of the type

$$\rho = a + bR + cR^2$$

where a , b , and c are empirical constants listed in Table 7. The molar volume of the AN-water system exhibited ideal behavior.

Table 7: Empirical parameters of the density–concentration equations for the AN-water system.

Temperature, K	a	$b \times 10$	$c \times 10$
323.2	1.48414	0.61416	–4.77017
328.2	1.48706	0.38516	–4.57249
333.2	1.45736	1.20525	–5.20867
338.2	1.52627	–1.04973	–5.46928
343.2	1.50200	–0.40526	–3.95904

Data source: [133]

The apparent molar volume of a solution is the sum of the partial molar volumes of the solute and of the solvent (water). A good correlation can be obtained by plotting the partial molar volumes against a concentration parameter χ

$$\chi = \frac{\sqrt{X}}{1 + \sqrt{X}}$$

where X is the mol fraction AN (Figure 13). This correlation was used at Olin Chemicals for calculating not only the densities of AN, HAN, and triethanolammonium nitrate solutions but also the densities of XM46 formulations with excess nitric acid [134]. The intercept at infinite dilution at 298 K (25 °C) is at 48.285 cm³/mol. See also [135].

Figure 13: Partial molar volumes of AN as a function of concentration parameter χ and temperature. (Reproduced and modified from [134], based on CRC Handbook p. D247 data.)

Density of AN Solutions in Ammonia

The densities of saturated solutions of AN in liquid ammonia are summarized in Table 8, based on two data sets from two different sources. The measurements were made

Table 8: Densities of saturated solutions of ammonium nitrate in liquid ammonia.

Temperature		Concentration	Density	Temperature		Concentration	Density
K	°C	Mass-% AN	g/cm ³	K	°C	Mass-% AN	g/cm ³
273.1	0	54.33	1.2640	293	20	66.1	1.3115
283.1	10	58.85	1.2909	313	40	73.3	1.3415
288.1	15	62.51	1.3003	333	60	80.2	1.3519

Data source: [136]

in closed bombs to prevent loss of ammonia at the higher temperatures. The vapor pressures of these solutions above room temperature are substantially above atmospheric pressure.

2.3.2.3 Density of Ternary Ammonium Nitrate Solutions

The density of the ternary AN/HN/H₂O system is shown in Figure 14. The temperature at which these density data were taken was not stated, but it is assumed that the densities are of the liquids at their freezing points.

Figure 14: Density of ternary AN/HN/H₂O oxidizer solutions. (Reproduced and modified from [121].)

The density of the ternary AN/nitric acid (HNO₃)/H₂O system can be calculated from the equation

$$\rho = 1.355 \text{ AN} + 1.722 \text{ HNO}_3 + 0.976 \text{ H}_2\text{O} + 0.188 \text{ AN HNO}_3 + 0.211 \text{ AN H}_2\text{O} - 0.173 \text{ HNO}_3 \text{ H}_2\text{O}$$

where ρ is the density in g/cm³, and AN, HNO₃, and H₂O are the mass fractions in the solution. The density ternary diagram is shown in Figure 15.

Figure 15: Density of ternary AN/HNO₃/H₂O oxidizer solutions. (Based on data from [127])

2.3.3 Compressibility and Equation of State of Solid Ammonium Nitrate

The equation-of-state properties and initiation behavior of neat AN were measured in a series of gas gun–driven plate-impact experiments on pressed neat ammonium nitrate at a density of 1.72 g/cm³ [137]. No evidence of initiation was observed under shock loadings up to 22 GPa. High-pressure XRD in diamond anvil cells provided some insight into the high-pressure phase behavior over a pressure range up to 25 GPa, as well as a static isotherm at ambient temperature. From the isotherm and thermodynamic properties at ambient conditions, an equation of state was developed for unreacted AN, which compared favorably with available experimental Hugoniot data on several densities of AN.

2.3.4 Vapor Pressure of Ammonium Nitrate

Ammonium nitrate sublimates and has a noticeable vapor pressure even before irreversible decomposition starts. The solid vaporizes by dissociation into ammonia and nitric acid. The vapor pressure of AN was measured using a transpiration–transference method [138]. A known volume of dry gas was passed slowly over heated (353–513 K [80–240 °C]) 30-g samples of AN and then through a condensation trap for durations of 1 to 120 h. The weight gain of the cold trap was identical to the weight loss of the sample, indicating that no gaseous decomposition products had formed

and escaped as a gas. The maximum weight loss was 15% during 40 min at 513 K (240 °C). The vapor pressure for the different phases of AN is illustrated in Figure 16. The green lines are the phase boundaries, and the Roman numerals designate the phase prevalent in this temperature range.

Figure 16: Vapor pressure of ammonium nitrate. (Reprinted and modified from [138], with permission from © 1962 American Chemical Society; permission conveyed through RightsLink.)

The vapor pressure of the solid and the liquid can be expressed by the following equations

$$\text{Solid} \quad \log p = 10.708 - \frac{4670}{T}$$

$$\text{Liquid} \quad \log p = 9.981 - \frac{4360}{T}$$

where p is the pressure in mmHg and T is the temperature in kelvin. The heats of vaporization calculated from the slopes are 178.6 and 166.9 kJ/mol (42.7 and 39.9 kcal/mol), respectively, for the solid and the melt.

It is difficult to measure the vapor pressure and dissociation pressure of AN due to incipient decomposition at temperatures where the vapor pressure and dissociation pressure become measurable [139].

Nevertheless, the dissociation pressure and enthalpy of liquid ammonium nitrate have been measured for the temperature range from 463 to 543 K (190–270 °C) [140]. From these data (Table 9), the free energy and entropy were calculated for the liquid and for the solid at 298 K (25 °C).

Table 9: Dissociation pressure of liquid ammonium nitrate.

Temperature		Dissociation pressure	
K	°C	Pa	mm Hg
461	188	432	3.25
478	205	991	7.46
489	216	1535	11.55
496	223	2100	15.80
510	237	3588	27.0
522	249	5448	41.0

Melting point 189.6 °C = 462.7 K

Data source: [140]

When plotting $\ln p$ vs. $1/T$, the average value of $d(\ln p)/d(1/T)$ corresponds to a heat of vaporization of 166.5 kJ/mol (39.8 kcal/mol), which is in approximate agreement with the values of 161.1–163.6 kJ/mol (38.5–39.1 kcal/mol) calculated from thermal data for this temperature range. The heat capacity of molten AN is 161 J K⁻¹ mol⁻¹ (38.5 cal °C⁻¹ mol⁻¹). The enthalpy of molten AN at the melting point (442.7 K [169.6 °C]) is 34.1 kJ/mol (8.15 kcal/mol) above that of solid AN (phase IV) at 298 K (that includes sensible heat for heating the solid to 442.7 K [169.6 °C]). In confirming the results of other investigations, the data indicated that the vapor of AN is completely dissociated into NH₃ and HNO₃ in the range of temperatures investigated.

Aerosol sampling by several groups indicates the presence of solid AN particles in the atmosphere. Long lifetime and long-range transport of these particles are predicted regardless of ammonia and nitric acid vapor concentrations. In support of atmospheric pollution studies in which AN aerosols contribute to nitrogen transport, microscopic anhydrous AN particles were levitated in a vacuum at 298 K (25 °C), and size and mass changes of the evaporating particles were monitored continuously *in situ* using light scattering and gravity balancing [141]. Fresh solid particles evaporated at a rate proportional to $1/r$, where r is an equivalent radius. Beyond 4 h, the rate was a constant $-0.06 \text{ \AA/s}$. These rates were consistent with those predicted from thermodynamics.

The total vapor pressure and vapor molecular weight of AN were determined by a torsion-effusion method, and vapor composition was determined by effusion-beam MS [142]. Total vapor pressures of AN were measured by using two effusion cells with different orifice diameters over the pressure range of 10^{-6} to 10^{-3} kPa, between 313 and 360 K. The equilibrium vapor-pressure equation was extrapolated from measurements with different orifice Knudsen cells, P1 and P2 cells:

$$\log P_T = (10.400 \pm 0.0002) - (4783.16 \pm 0.07)/T$$

where P_T is the pressure at temperature T in kPa and T is the temperature in kelvin. The molecular weights of AN vapor were measured as 48.7 g/mol for P1 cells and 50.7 g/mol for P2 cell, both of which are much less than the theoretical molecular weight of AN (80.04 g/mol). This significant difference in molecular weight suggests that there is some disproportionation of AN in the vapor phase. Mass spectroscopic analysis revealed that NH_4NO_3 decomposes to NH_3 and HNO_3 , but none of the expected N_2 , O_2 , and H_2O decomposition products were found during vaporization. The partial pressures of the three vapor-phase species (NH_4NO_3 , NH_3 , and HNO_3) that were evolved during vaporization of NH_4NO_3 sample were determined as $P_{\text{NH}_4\text{NO}_3}/P_T = 0.1490$, $P_{\text{NH}_3}/P_T = 0.2911$, and $P_{\text{HNO}_3}/P_T = 0.5599$.

The sublimation pressures of $\text{NH}_4\text{NO}_3(\text{g})$ over the range 321–360 K were derived from the total pressures measured by a torsion-effusion method and the NH_4NO_3 partial pressure [143].

The vapor pressure of AN was measured at 373–433 K (100–160 °C) using an isothermal thermogravimetric weight loss method and compared to that of guanidinium nitrate and urea nitrate [144]. The Clapeyron equation for urea nitrate vapor pressure is

$$\ln P = 35.141 - 12690/T$$

where P is the pressure in Pa and T is the temperature in kelvin. For a temperature of 298 K, this equation gives a vapor pressure of 5.98×10^{-4} Pa = 4.49×10^{-6} mm Hg. From the slope of this equation, an enthalpy of sublimation was calculated as 106 kJ/mol.

2.3.5 Solubility of Ammonium Nitrate

2.3.5.1 Solubility of Ammonium Nitrate in Water

Ammonium nitrate is quite soluble in water. This makes it easy to clean processing equipment that was used for grinding or coating AN, and it also would be easy to demilitarize AN-based propellant grains by extracting the oxidizer with water. The solubility of AN in water is summarized in Table 10.

Table 10: Solubility of ammonium nitrate in water

2.3.5.2 Solubility of Ammonium Nitrate in Liquid Ammonia

Ammonium nitrate dissolves readily in liquid ammonia, forming a liquid that exists at room temperature with a vapor pressure only slightly above atmospheric pressure. Such solutions are called Divers' solution N. Similar solutions with even lower vapor pressures are formed with ammonium thiocyanate. Solutions of AN in liquid ammonia are potentially very cheap and very clean monopropellants, but they are difficult to ignite and sustain (*Encyclopedia of Monopropellants*). The vapor pressure of a saturated solution reaches atmospheric pressure at room temperature (293 K [20 °C]). It is therefore relatively easy to handle Divers' solution N in glassware in the laboratory. The

solubility of AN in liquid ammonia is summarized in Table 11 (based on data from two different sources, covering different temperature ranges). The freezing-point diagram of the AN/NH₃ system does not show any evidence for the formation of ammoniates with discrete AN:NH₃ ratios.

Table 11: Solubility of ammonium nitrate in liquid ammonia.

Temperature		Concentration		Temperature		Concentration
K	°C	Mol-% AN	Mass-% AN	K	°C	g AN/100 mL solution

2.3.5.3 Solubility of Ammonium Nitrate in Nitric Acid

Ammonium nitrate is reported to be appreciably soluble in aqueous and concentrated nitric acid; solutions of 50 mass-% AN in anhydrous nitric acid are commonly used in the manufacturing of explosives. Heat is evolved when AN is dissolved in 99.6% HNO₃, but heat is absorbed if AN is dissolved in water. Dissolving AN in HNO₃ would lower the vapor pressure and freezing point of the acid but would not improve its oxygen content.

The solubilities of AN (and alkali metal nitrates) in HNO₃ at 273–303 K (0–30 °C), the vapor pressures of these solutions at 273–288 K (0–15°), and their densities, electrical conductivities, and viscosities at 298 K (25 °C) were measured [145].

The phase diagram of the system AN/HNO₃ is shown in Figure 17. Ammonium nitrate forms 1:1 and 1:2 adducts with HNO₃. The 1:2 adduct is evident from a distinct peritectic in the phase diagram. Ammonium nitrate crystallized from a solution in fuming nitric acid forms prismatic needles of NH₄NO₃•2HNO₃ that melt at 302–303 K (29–30 °C) or NH₄NO₃•HNO₃ that crystallizes in the shape of leaflets or plates that melt at about 285 K (12 °C).

Figure 17: Phase diagram of the system ammonium nitrate/nitric acid. (Reproduced and modified from [136])

2.3.5.4 Solubility of Ammonium Nitrate in Organic Solvents

If sufficient AN could be dissolved in organic solvents, this would make very economical potential monopropellants. Ammonium nitrate is soluble to a modest extent in the lower alcohols and amines but not enough to make a full-fledged monopropellant.

The solubility of AN in methanol is better than in ethanol. At 291.6 K (18.5°C), 100 g methanol will dissolve 16.3 g AN, and at 293.6 K (20.5°C) it will dissolve 17.1 g AN. At 293.6 K (20.5°C), ethanol will dissolve only 3.8 g AN. At 353 K (80°C), absolute ethanol will dissolve 10.5 g AN per 100 g solvent. The solubility can be improved by adding a little water.

2.3.6 Hygroscopicity of Ammonium Nitrate

One of the main disadvantages of AN for use in rocket propellants is its hygroscopicity [146]. Ammonium nitrate left open in the air will soon absorb moisture and become deliquescent. Cycles in ambient humidity and temperature will cause it to cake. Various additives and coatings have been tested to reduce hygroscopicity and prevent caking of AN during storage.

Samples of 40-mesh AN and 100-mesh AN stabilized with 10% KN were exposed to controlled-humidity atmospheres in a desiccator for 5 d and weighed at the end of

the tests [147]. There was no measurable weight gain below 51% relative humidity, but beginning weight gain was noted at 52% relative humidity. KN-stabilized AN absorbed more moisture than pure AN. At 75% relative humidity, AN absorbed 4.8% moisture after 5 d, and KN-stabilized AN absorbed 10% moisture after 5 d.

Eight different samples of AN were tested for hygroscopicity at relative humidity levels of 60, 70, 80, and 90% and between 301 and 303 K (28 and 30 °C), including a sample of chemically pure reagent-grade AN, four commercial-grade samples that met military specifications, and three samples with phase-stabilizing additives [148]. Most of the samples of AN were coated, some were manufactured by a process producing prills, and clay coatings were applied in two cases. The results indicated that the AN that contained the least amount of impurities or additives was also the least hygroscopic.

Two types of tests were used to characterize the moisture sensitivity of AN. One test, a static test, consisted of Petri dishes filled with 5-g AN samples that were placed in desiccators kept at constant humidity and 303 K and were weighed periodically. In the other test, a dynamic test, a flow of moisture-conditioned air was continuously passed over AN samples for 2 h. The advantage of the dynamic method was that the samples could be weighed continuously, without opening a desiccator and disturbing the equilibrium conditions. Supplementary data were obtained by drying the moist samples at 373 K in dry air to constant weight and determining the rate at which water was removed. In a static test, reagent-grade AN gained 14.4% weight in 60% relative humidity, 51.8 in 80% relative humidity, and 67 in 90% relative humidity after 160 h. In a dynamic test, specification-grade AN gained 6% weight in 90% relative humidity after 2 h.

Other hygroscopicity results are summarized in Table 12. The weight gain of AN stored in thin layers at 22.2 °C (72 °F) at different relative humidities is summarized in Table 13.

The vapor pressure of a saturated solution of AN in water is 1.236 kPa (9.3 mm Hg) at 293 K and is 1.54 kPa (11.6 mm Hg) at 298 K, corresponding to relative humidities of 66 and 61%, respectively.

2.3.7 Thermal Conductivity of Ammonium Nitrate

The thermal conductivity of solid AN is $0.205 \text{ kcal m}^{-1} \text{ h}^{-1} \text{ }^{\circ}\text{C}^{-1}$, which is equivalent to $0.1375 \text{ BTU ft}^{-1} \text{ h}^{-1} \text{ }^{\circ}\text{F}^{-1}$.

2.3.8 Optical Properties of Ammonium Nitrate

2.3.8.1 IR Spectra of Ammonium Nitrate

Vibrational spectroscopy of the ammonium ion in crystals is important for analyzing oxidizers for contaminants, for identifying AN residues at accidental explosion sites, and for explaining some of the phase changes that occur while ramping up or down the storage temperature of the crystals. IR spectroscopy is also used in studying the decomposition of AN and the effectiveness of catalysts and stabilizers in accelerating or retarding the decomposition of AN. Therefore, it is important to have good IR spectra of the undecomposed, pure ammonium nitrate.

Hydrogen bonding and motions of the ammonium ion in crystals are two aspects that have been studied with some success using IR, Raman, and nuclear magnetic resonance (NMR) spectroscopy. These characteristics of the ammonium ion are of exceptional importance in the case of AN since they are believed to play a key role in determining the structures of the five crystalline modifications that occur at atmospheric pressure and in the transitions between these phases. At high temperatures, NH_4^+ and NO_3^- ions are supposed to undergo nearly free rotation, and the phase transitions are associated with the freezing and thawing of the rotational degrees of freedom. Unlike the phase transitions of CsNO_3 and RbNO_3 , transitions of NH_4NO_3 are accompanied by more drastic changes in the IR spectrum. The changes in the IR spectra can be followed while going from the highly ordered phase V to phase I (where the ions rotate freely) through the intermediate phases. Some IR absorption bands disappear, and others start to show up. The symmetries and structures of all these phases can be modeled theoretically and determined using supplementary methods (XRD, NMR, XPS). The four modes of NH_4^+ oscillations are commonly described as $\nu_1'(\text{A}_1)$, $\nu_2'(\text{E})$, $\nu_3'(\text{T})$, and $\nu_4'(\text{T})$, corresponding to symmetric stretching, symmetric deformation, asymmetric stretching, and asymmetric deformation modes, respectively. Vibrational coupling may occur between factor-group modes that originate in the in-

ternal vibrations of dissimilar ions, specifically between modes of the same symmetry derived from the $\nu_3(\text{NO}_3)$ and $\nu_4'(\text{NH}_4)$ vibrations. Certain vibrational assignments initially proposed for AN were in error.

The IR spectra of solid crystalline films of AN were measured at temperatures ranging between the melting point (442 K [169 °C]) and liquid air temperature (83 K [−190 °C]) [150]. Four different spectra were obtained that were shown to belong to phase I, II, IV, and (very probably) VII. The existence of phase VII has been disputed by other investigators. Phases III and V were not encountered under the conditions of this experiment. Only the transitions $\text{I} \leftrightarrow \text{II}$ (398 K [125 °C]), $\text{II} \leftrightarrow \text{IV}$ (323 K [50 °C]), and $\text{IV} \leftrightarrow \text{VII}$ (213 K [−60 °C]) were observed in the IR spectra. A spectrum measured at 83 K (−190 °C) after rapid cooling was assigned to a mixture of phases IV and VII. The symmetry properties of the different phases are reflected in their IR spectra.

Phase transitions of NH_4NO_3 (V-IV-III-II-I) have been studied by IR spectroscopy with the material sublimed onto KRS-5 ATR crystals [151] (Figure 18). At that time, this was the best set of IR spectra for AN in all its five phases.

Figure 18: IR spectra of the five phases of AN in the range 2000–4000 and 700–2000 cm^{-1} .

Infrared spectra of NH_4NO_3 , $\text{NH}_4^{15}\text{NO}_3$, and ND_4NO_3 were measured as nujol mulls, and the assignments of some vibrational bands of ammonium nitrate were tabulated as shown in Table 14; amendments were suggested to some previous work of other authors on this subject [152]. In dry samples, transformation of AN proceeds directly from phase IV to phase II at a temperature of about 325 K.

Infrared spectra showing the symmetric stretching vibration band γ_1 of the nitrate ion (although it is symmetrical, it is rendered weakly IR-active by the crystal field) were recorded for sample pressures up to 6 kbar at temperatures ranging between room temperature and liquid nitrogen temperature, and a pressure–temperature phase diagram for the λ -transition of AN was obtained by this method [153]. The spectra at low temperatures and low pressures were due to mixtures of phase IV and phase VII.

The near-IR spectrum of AN displayed a doublet located at 1569 and 1642 nm due to the first overtone of symmetric and anti-symmetric NH_4 stretching vibrations ($2\nu_s\text{NH}_4$, $2\nu_a\text{NH}_4$), as well as a wide doublet located at 2031 and 2133 nm due to the first combination region, i.e., the combination of NH_4 stretching and NH_4 bending modes ($\nu\text{NH}_4 + \delta\text{NH}_4$). An additional band located at 1270 nm, whose vibrational assignment is unclear, was observed in the near-IR spectrum of AN [154].

2.3.8.2 Raman Spectra of Ammonium Nitrate

Isotope substitution allows us to assign molecular vibrations in AN crystals. The vibrations and Raman lines are different for the deuterated AN and are different for some of the polymorphic phases. The laser Raman spectra of NH_4NO_3 and ND_4NO_3 were measured between 210 and 320 K, and it was shown that the phase transition $\text{V} \rightarrow \text{IV}$ is probably a λ -transition that occurs gradually between 210 and 256 K with an abrupt change at 256 K [155]. The λ -transition is due to rotational disorder of ammonium ions, as shown by the localized disorder mode at 172 cm^{-1} . The spectrum of phase IV showed clear evidence of T and L components of the nitrate ion asymmetric stretch, but this is inconsistent with the assigned space group *Pmmn*. It was attempted to explain this by way of a thermally induced $\text{IV} \rightarrow \text{III}$ transition.

The temperature dependence of the low-frequency Raman spectrum of AN in its solid phases IV, II, and I and also in its melt was measured, and librational modes were observed in phases IV and II but disappeared in both phase I and the melt [156]. The results indicated that the NO_3 group is almost freely rotating in the solid phase I.

Raman spectra of NH_4NO_3 and ND_4NO_3 were studied from 250 to 420 K [157]. The results showed that there are four phases separated by first-order transitions. No evidence of the previously reported phase II' was observed. In phase I, the high-temperature phase, the NH_4^+ groups are in a free rotation and the nitrate groups are likely in random reorientation among 12 equivalent positions. In phase II, the NH_4^+ groups are in rapid random reorientation under the local force field of S_4 symmetry. The nitrate groups are in hindered rotation but are disordered, with one of the O—N bonds directed in one sense or the other along the *c*-axis. In phase III, the absence of the librational mode indicated that the NH_4^+ groups are in nearly free rotation, but the rotational motion is restricted by the local force field of C_3 symmetry. The nitrate groups are probably ordered as suggested by the well-polarized character of the modes associated with the nitrate groups. In phase IV, the nitrate groups are ordered with their molecular planes perpendicular to the *b*-axis. The NH_4^+ groups are in orientational disorder but may undergo hindered rotations.

Extending this work to lower temperatures, Raman spectra of NH_4NO_3 and ND_4NO_3 were recorded from room temperature down to 11K [158]. A sluggish transition from phase IV to phase V was clearly observed, but no evidence was found for another low-temperature phase. Large splitting of the ν_3 mode indicated that the inter-ionic interaction between NH_4^+ and NO_3^- is rather strong in both phases.

Polarized Raman spectra of single crystals of AN were observed for the room-temperature phase $\text{NH}_4\text{NO}_3(\text{IV})$ [159]. The spectra in the low-frequency lattice vibration region as well as in the internal vibration region were well interpreted based on a *D2h13* structure. Raman spectra of powdered samples were measured at various temperatures covering the entire range of phases I–V. A characteristic feature in the Raman spectrum could be identified for each phase. An abrupt spectral change occurred in the phase transition, indicating a first-order transition. The splitting of Ag and B1g

components of ν_3 (asymmetric stretching mode of NO_3^- ion) in NH_4NO_3 was quite large due to the strong inter-ionic interaction between NH_4^+ and NO_3^- ions.

The Raman spectra of phase III ammonium nitrate and isotopomeric materials showed that $\delta(\text{NH}_2)$ and $\nu(\text{N}-\text{O})$ vibrations are coupled together throughout the lattice [160]. This observation may be relevant to both the phase changes of AN and its detonation properties.

See also [161, 162]. Raman spectra provided spectroscopic evidence for a phase II-like intermediate during the course of the $\text{IV} \rightarrow \text{III}$ phase transition in ammonium nitrate, [163] but other investigators dispute its existence.

The temperature dependence of the Raman spectra of AN in the lattice-mode region below 200 cm^{-1} was measured at high temperatures through the tetragonal II to cubic I phase transition at 398 K [164]. As the $\text{II} \rightarrow \text{I}$ transition was approached, a pronounced softening of the librational mode was observed as well as a broadening of the line width.

Low-temperature Raman spectra of phase V AN were used to interpret the crystal structure and hydrogen bonding in the crystal [165]. The phase transition $\text{V} \rightarrow \text{orthorhombic IV}$ was observed over a 100-K range below the established transition temperature of 255 K. The phase transition may be due to a change in hydrogen bonding and gradual reorientation of NO_3^- ions in the crystal lattice. It was shown that there is heteroionic vibrational coupling between NH_4^+ and NO_3^- at 1400 cm^{-1} . Assignments of Raman bands to internal (intramolecular) and external (lattice movements) modes of vibration could be made by using isotope effects when substituting ^{14}N with ^{15}N and ^1H with ^2D .

2.3.8.3 Refractive Index of Ammonium Nitrate

The room-temperature refractive indices of AN were measured in 1933, and very little work has been done since then to extend measurements to other phases. The birefringence of these modifications is very high, with that of phase III being somewhat lower than that of the others. The index of refraction of AN is 1.413 at the Na_D line and 1.611 at the wavelength 587.6 nm of the He line.

2.3.9 Electrical Properties of Ammonium Nitrate

2.3.9.1 Electrical Conductivity of Ammonium Nitrate

The electrical conductivity of dehydrated AN pellets, partially fused in the cold, was measured at 1–600 bars and 355–442 K (82–169 °C) [166]. In this temperature range, AN exists in two different crystalline forms. Measurements were made under decreasing and then increasing temperatures. A hysteresis loop was observed that was related to the slow structural transformation. At 378.1 K (105 °C), the molar volume of formation of defects, ΔV_F , was calculated to be of the order of 26 cm^3 . The molar volume, V_m , was 47 cm^3 . As long as the ratio $\Delta V_\text{F}/V_\text{m}$ was <1 , the salt contained mainly Frenkel defects.

2.3.9.2 Dielectric Constant of Ammonium Nitrate

A pyroelectric, dielectric, and differential thermal analysis of the high-temperature phase transition II-I of AN polycrystalline samples was carried out in the temperature range 383–438 K (110–165 °C) [167]. The pyroelectric current showed a very strange behavior with temperature in which the pyrocurrent started in the positive direction, decreased during the increase of temperature, and then reversed its direction after passing through a zero value. The dielectric constant, dielectric loss, and resistivity measurements indicated that this phase transition is due to order–disorder phenomena in which a strong lattice–electric dipole interaction takes place. Thermal analyses (DTA and TGA) were also used to obtain the thermodynamic and kinetic data of this transition. This analysis showed that the heat of transition is 4.35 kJ/mol (1.04 kcal/mol) and the strain energy is $E_s = 2272 \text{ J/mol}$ (543 cal/mol).

2.3.10 Magnetic Properties of Ammonium Nitrate

2.3.10.1 Nuclear Magnetic Resonance Spectra of Ammonium Nitrate

Studies of the line width of proton magnetic resonance in solid NH_4NO_3 indicated that the NH_4^+ ions have rotational and translational freedom. Similar results were obtained for the deuterated analog ND_4NO_3 . Because the spin relaxation mechanisms of protons and deuterons are different, measurements of the two compounds may give more information about the mobility of the ions.

Measurements of the spin-lattice relaxation time T_1 of protons in solid NH_4NO_3 between 192 and 308 K gave additional information on the temperature threshold when the rotations are thawing [168]. Additional NMR pulse experiments performed under applied hydrostatic pressures between 1 and 680 atm bracket the regime of free rotation. The intramolecular rotation of groups within molecules seemed to be insensitive to pressures within this range, and the rotation of entire molecules in the solid state is pressure dependent in varying degrees. The observed pressure coefficients of T_1 in AN and other solids were related to the thermal expansion coefficient of the lattice by a simple model that postulated a localized lattice expansion as an important step in the reorientation process.

Hovi, Järvinen, and Pyykkö measured the deuteron magnetic resonance line-widths in ND_4NO_3 between 100 and 403 K [169]. They obtained values of 255, 308.5, 366, and 400.5 K with a maximum uncertainty of $\pm 2 \text{ K}$ for the transformation temperatures of $\text{V} \rightarrow \text{IV}$, $\text{IV} \rightarrow \text{III}$, $\text{III} \rightarrow \text{II}$, and $\text{II} \rightarrow \text{I}$ phase transformations, respectively.

The spin-lattice relaxation times T_1 for protons and deuterons in polycrystalline NH_4NO_3 and ND_4NO_3 at temperatures between 80 and 430 K were measured using the NMR pulse method [170]. From the measured values of T_1 , the activation energies for the reorientation motions of NH_4^+ and ND_4^+ ions below 200 K were calculated to be $8.67 \pm 0.46 \text{ kJ/mol}$ ($2.07 \pm 0.11 \text{ kcal/mol}$) and $10.72 \pm 0.96 \text{ kJ/mol}$ ($2.56 \pm 0.23 \text{ kcal/mol}$),

respectively. The quadrupole coupling constant $2Qq/h$ of the deuteron in ND_4^+ ion was 194 ± 30 kc/s.

Measurements of the proton spin-lattice relaxation times (T_1 , $T_{1\rho}$) have been made to study the translational and reorientational motions of the ammonium ions in AN crystals in several solid phases [171]. At the plastic-to-brittle phase transition at 398 K, the correlation time for translational diffusion of the NH_4^+ ion increased by more than three orders of magnitude. The self-diffusion constants for NH_4^+ in phases II and I obtained from these correlation times were in close agreement with the diffusion constants reported from electrical conductivity measurements in phases II and I.

The five solid phases of AN and transitions between these phases were studied using solid-state ^{15}N magnetic angle spinning (MAS) and static NMR [172, 173]. The $IV \leftrightarrow III$ conversion temperature, often given as 295 K (32°C), can vary depending on the moisture content and thermal history of the sample. Other transitions can also exhibit hysteresis between heating and cooling.

The temperature dependences of the ^{14}N nuclear quadrupole resonance frequencies of NH_4NO_3 in phases II, III, IV, and V were measured with the help of the 1H - ^{14}N nuclear quadrupole double-resonance technique [174]. The experimental results supported the proposed crystal structures and levels of disorder and mobility in the various crystallographic phases.

^{14}N MAS NMR spectroscopy and the associated ^{14}N quadrupole coupling data can be used for characterizing phase transitions between two solid phases. For AN, the transition between the phases IV and III at about 35°C and the phases themselves were studied by ^{14}N MAS NMR using NH_4^+ as well as the NO_3^- ion as probes [175]. Frictional heating caused the samples to warm up. The ^{14}N quadrupole coupling constants and asymmetry parameters for both the NH_4^+ and NO_3^- ion determined from these spectra showed large changes upon transition between the two phases. Also, the transition exhibited the effect of hysteresis with a deviation of about 10°C for the transition temperature. ^{14}N MAS NMR is a useful tool for characterizing phase transitions of nitrogen compounds from ^{14}N quadrupole coupling data.

The main components of industrial explosives that are sometimes diverted for illicit actions are TNT and AN. Nuclear quadrupole resonance (NQR) can be used for the detection of AN and TNT [176]. It is difficult to attenuate outside interference signals under conditions of an industrial environment.

2.3.11 Crystal Structure of Ammonium Nitrate

Most of the work dealing with the molecular structure of AN is related to the phase changes that AN undergoes at various temperatures. Each time AN changes to a different phase, so does its molecular structure. The molecular structure of AN has been determined experimentally using XRD, neutron diffraction, IR spectroscopy, and Raman spectroscopy. The measurements have been complemented by theoretical modeling using computational chemistry.

Initially, the crystal structures of all five phases (for the hydrogenous form) were studied using XRD, but only phase IV [177], phase II [178], and phase I [179] had been completely determined by neutron diffraction methods.

The crystal structure parameters and crystallographic assignments of the various phases of AN are summarized in Table 15.

Table 15: Phase-dependent crystal structure properties of ammonium nitrate crystals.

Phase I Properties

The high-temperature phase I of pure AN is stable above 398 K and, just before melting, is a plastic phase with a cubic structure having rotational disorder of the nitrate groups [184]. The lattice parameter of the phase I cubic structure with space group *Pm* $\bar{3}$ *m* is *a* = 0.437 nm and *Z* = 1 [75].

X-ray diffuse scattering measurements due to the orientational disorder of NO₃[−] ions in the cubic phase of AN showed that the observed disk-like diffuse maxima are explained by a 12-orientation model [180]. The local order slightly deviates from what is expected from an idea of the atomic packing. The configurational entropy was calculated from five crystal parameters, and the result was not incompatible with the calorimetric measurement results.

Phase II Properties

The tetragonal structure (*P* $\bar{4}$ *2*₁*m*) of phase II was reported to be stable between 357 and 398 K [185, 186]. The lattice parameters of phase II are *a* = 0.57193(1) nm and *c* = 0.49326(1) nm, *Z* = 2 [178].

Phase III Properties

The crystal structure of phase III is orthorhombic and is stable between 305.3 and 357 K. The space group is *Pnma*, with $a = 0.77184(1)$ nm, $b = 0.58447(1)$ nm, and $c = 0.71624(1)$ nm, $Z = 4$, based on a neutron diffraction study [181].

The crystal structure of stabilized AN phase III at room temperature was examined by neutron diffraction using a single crystal containing 5% KNO_3 in solid-solution form [187]. The space group is *Pnma*, with $a = 7.6772$, $b = 5.8208$, $c = 7.1396$ Å, $Z = 4$. The ammonium ions are thermally disordered into two orientations, displaced by an angle of approximately 42° about an axis parallel to the c axis.

Phase IV Properties

Phase IV is stable between 255 and 305 K, and the structure is orthorhombic [64] and [177], with space group *Pmmn* with $a = 0.57574(1)$ nm, $b = 0.54394(1)$ nm, and $c = 0.49298(1)$ nm, $Z = 2$.

Phase V Properties

The structure of phase V was initially reported as tetragonal ($P4_2$) [188] but was later redetermined to be orthorhombic with a space group of *Pccn* by [182]. Phase V is an orthorhombic structure and is stable below 257 K with $a = 0.79804(1)$ nm, $b = 0.80027(1)$ nm, and $c = 0.98099(1)$ nm, $Z = 8$ at 233 K. Other investigators [183] measured $a = 0.78850(2)$ nm, $b = 0.79202(2)$ nm, and $c = 0.97953(2)$ nm, $Z = 8$ at 78 K.

A neutron diffraction study showed that phase V with orthorhombic structure was stable down to at least 5 K [189].

2.3.11.1 Phase Transitions

The phase transitions can be visualized by conducting a temperature-resolved series of XRD scans in which samples are heated or cooled stepwise, measuring the XRD patterns after each temperature step [190–194]. The curves for the elementary cell parameters of the different phases as a function of temperature exhibit crystal lattice details and elucidate expansion and transition mechanisms. They are used for the calculation of the volume changes during the transitions and the volumetric and linear expansion coefficients. Figure 19 illustrates a series of temperature-resolved XRD patterns. This method is particularly useful for evaluating the effectiveness of phase-stabilizing additives to AN.

Dry AN did not show a transition into phase III, but moist AN did [195]. The IV $\rightarrow$ III transition occurs through expansion of IV, where adjacent (001) layers shift in opposite directions. The shift is strongest for the tilted NO_3^- group.

Using energy-dispersive XRD for studying AN phase change between phase II and phase I, it was noted that the II/I phase transition is continuous [196].

Several series of diffraction patterns were measured with dry powdered AN from 323 to 333 K (50–60 °C) on heating and from 323 to 313 K (50–40 °C) on cooling [197]. The variations of lattice constants allow one to observe the phase transitions. On heat-

Figure 19: Series of AN XRD patterns measured after stepwise heating from -70 to $+150$ °C.

(Republished from [194], with permission of © 2005 John Wiley Sons – Books; permission conveyed through Copyright Clearance Center Inc.)

ing, the phase transition IV/II occurs between 325 and 329 K (52 and 56 °C). In this temperature interval, both phases co-exist. On cooling, simultaneous transitions II/IV and II/V occur, with phase V slowly transforming into phase IV.

The phase transition IV/II of AN was investigated using XRD [198]. All phase transitions are very sensitive to moisture, and only a few XRD and energy-dispersive X-ray analysis (EDAX) phase-change experiments have been performed with absolutely dry samples, except in a series of experiments at the Fraunhofer Institute for Chemical Technology (ICT) in Germany [199]. A series of XRD spectra were measured in 2 °C intervals while ammonium nitrate was cycled between 203 and 353 K (-70 and $+80$ °C) or 203 and 423 K (-70 and $+150$ °C). On cooling from 423 K, the phase transitions I/II/IV/V and, on heating, the same transitions in reverse order occurred as expected. After the sample was heated to 353 K, phase II changed simultaneously into the phases IV and V below 323 K. Further cooling to 203 K changed the portion still existing in phase IV into phase V. During the succeeding heating cycle, an incomplete transition V/IV was followed by the transitions IV/II and V/II.

2.3.11.2 Pressure Effects on Molecular Structure

The effects of compression on phase IV AN were calculated at pressures up to 600 GPa [200]. Over this pressure range, the crystal volume was compressed by 71% of the equilibrium volume. Anisotropic behavior was observed when calculating the lattice parameters a , b , and c at different pressures. Compressibility effects were similar for the a and c direction, but the compressibility in the b direction was much higher. This can be explained by the fact that there are relatively strong $\text{NH}\cdots\text{O}$ bonds in the ac plane and weaker $\text{H}\cdots\text{O}$ bonds in the b direction.

2.3.11.3 Experimental Study of Molecular Structure of Ammonium Nitrate

Experimental methods for the study of the molecular structure of AN include XRD, neutron diffraction, IR spectroscopy, and Raman spectroscopy. Most publications deal with more than one phase of AN, but with increasing specialization some publications deal with only one phase transition or with a particular phase that is stable in a given temperature range.

The crystal structure of room-temperature phase IV has been determined by neutron diffraction. The crystal consists of hydrogen-bonded chains

parallel to the a axis. The chains are linked by somewhat weaker hydrogen bonds $\text{H}(2)\cdots\text{O}(1)$ to form sheets perpendicular to the c axis. Adjacent sheets are held together by van der Waals forces. The NO_3^- ions are distorted from the trigonal symmetry. The NH_4^+ ions are bound with two short ($\text{H}(2)\cdots\text{O}(1)$ distance = 0.205 nm) and two longer ($\text{H}(2)\cdots\text{O}(1)$ distance = 0.216 nm) hydrogen bonds. The tetragonal phase V belongs to the space group $P4_2$ with $Z = 8$. It seems to be the most ordered phase of AN.

Ammonium nitrate was temperature-cycled in consecutive steps in a high-temperature device mounted on an X-ray goniometer [201]. Diffraction patterns were measured at each temperature, using a Si-Li detector together with a multi-channel analyzer. The results strongly supported the existence of a phase II'. They showed that the phase change IV/III goes via a transition state similar to or consistent with phase II'.

The instrument developed at ICT in Germany allows the observation of the phase transitions of dry AN with XRD under cyclic thermal loading [202, 203]. The capabilities of this new instrument were demonstrated on the examples of AN phase changes. AN was subjected to two different temperature cycles: **(1)** $20 \rightarrow 150 \rightarrow -70 \rightarrow 150^\circ\text{C}$ and **(2)** $20 \rightarrow 80 \rightarrow -70 \rightarrow 80^\circ\text{C}$. Crystal structure changes were registered by continuously recording the XRD patterns. Several different phase-change paths were observed: For temperature cycling between -70 and 150°C , the sequence of phase conditions is $\text{IV}(20^\circ\text{C}) \rightarrow \text{II} \rightarrow \text{I}(150^\circ\text{C}) \rightarrow \text{II} \rightarrow \text{IV} \rightarrow \text{V}(-70^\circ\text{C}) \rightarrow \text{IV} \rightarrow \text{II} \rightarrow \text{I}(150^\circ\text{C})$. If the upper temperature limit is lowered to 353 K (80°C), the expected phase sequence $\text{IV}(20^\circ\text{C}) \rightarrow \text{II}(80^\circ\text{C}) \rightarrow \text{V}+\text{IV} \rightarrow \text{V}(-70^\circ\text{C}) \rightarrow \text{V}+\text{IV} \rightarrow \text{II}(80^\circ\text{C})$ differs from the expected path. See also [204].

One of the methods to verify experimental and theoretical molecular structure results is isotope substitution and comparison of the isotope-substituted molecule to the natural molecule. In the case of AN, isotope substitution studies have mostly been done by substitution of hydrogen with deuterium. The neutron powder diffraction data of cubic ND_4NO_3 cannot distinguish between the two best orientation models put forward for rigid NO_3 [179].

The structure of ND_4NO_3 phase V was determined by neutron powder diffraction [183]. The IR spectra of the ^1H and ^2H ammonium salt are quite different. Substitution of the ^{14}N with ^{15}N has only minor effects. However, N-isotope and O-isotope substitution has been used to resolve questions about the origin of the N-atoms in the formation of N_2O by decomposition of AN [205, 206]. The results showed that the decomposition of AN to give N_2O proceeds practically entirely by a bond formation between the two nitrogen atoms of the two different groups present, not by the interaction of similar groups. It has been found that small amounts of water were necessary to initiate the decomposition of AN. $^{15}\text{NH}_4\text{NO}_3$ has been found to yield exclusively the isomer $^{15}\text{N}^{14}\text{NO}$.

2.3.11.4 Thermal Analysis of Phase Changes of Ammonium Nitrate

Many studies of the thermal effects during phase changes in AN have been combined with other methods, such as XRD or spectral analysis of the different phases. Here we summarize publications that have relied on thermal analysis (DTA, DSC) alone to obtain information on phase changes in AN. These methods are used to study solid state phase changes that may be endothermic or exothermic. These methods are also used to study the effectiveness of stabilizing additives.

A modified DTA technique was employed for a study of the various transformations in deuterated AN [207]. The equilibrium temperatures in the transformations $\text{IV} \leftrightarrow \text{III}$, $\text{III} \leftrightarrow \text{II}$, and $\text{II} \leftrightarrow \text{I}$ were observed as 302.8, 361.52 ± 0.06 , and 400.58 ± 0.04 K, respectively. The melting point of ND_4NO_3 was found to be 1.2 K higher than that of NH_4NO_3 due to the isotope effect. In the $\text{I} \leftrightarrow \text{II}$ transformation, thermal hysteresis was not observed as indicated earlier by others in the case of NH_4NO_3 . Superheating of modification II was not found to take place at the transformation $\text{II} \rightarrow \text{I}$, while supercooling of modification I was observed at the transformation $\text{I} \rightarrow \text{II}$. Considerable superheating and supercooling proved characteristic of the III and II phases at the $\text{II} \leftrightarrow \text{III}$ transformation. Small thermal hysteresis was observed during this transformation. The $\text{III} \leftrightarrow \text{IV}$ transformation was also found to be associated with small thermal hysteresis. Modifications III and IV of ND_4NO_3 supercooled by 0.7 and 0.5 K, respectively. Consideration of the effect of deuteration on the Gibbs function of various modifications of AN indicated that the interaction of the NH_4^+ group with the lattice seemed to be strongest in modification III.

The transformation from phase IV to some other phases occurs in more than one step below 324 K (51 °C) and is accompanied by endothermic peaks if the sample is

heated after prolonged storage at room temperature or after slow cooling [208]. Removal of moisture shifts the transition temperature closer to 324 K (51 °C). Foreign materials, crystal defects, and thermal treatment history influence the transition from phase IV to phase II or III. There may be metastable phases that delay or smudge the clean transition from one phase to the other.

In addition to measuring the temperature at which the phase transitions occur, it is also important to know the enthalpy changes occurring at each step (Section 2.3.12.3).

Ammonium nitrate solid-phase transition paths between phases IV, III, and II were analyzed by XRD and DSC [209]. The analysis of the XRD and DSC measurements proved that the different phase transition paths are of structural origin.

2.3.11.5 Theoretical Modeling of the Molecular Structure of Ammonium Nitrate

Computational chemistry has gained acceptance to the point that some chemists consider it a replacement for experimental measurements, whereas others consider it only as a supplement to experimental studies. Every once in a while, the two methods agree.

A force field–based molecular model for the description of the III and IV phases of AN was used to illustrate the development of molecular modeling techniques for energetic materials [210]. In addition to describing the lattice forces, the model also correctly predicted the dominance of (200) faces in crystals grown at low supersaturation.

Interatomic potentials were derived for ammonium and nitrate molecular ions in AN crystals, using empirical fitting to known properties of ammonium halides and alkali nitrates, and were used to calculate crystal and lattice properties of AN, which were then compared with available experimental data [211]. The potentials were then used to model the low-temperature phase (phase V) of AN.

Plane-wave *ab initio* calculations based on density function theory and a pseudopotential method were used to investigate the structural and electronic properties of phases V, IV, III, and II of AN crystals [200]. The optimizations of the crystal structures were done with full relaxation of the atomic positions and lattice parameters under the experimentally determined crystal symmetries. For phases V, IV, and II, the predicted crystal structures were found in good agreement with those determined experimentally by neutron diffraction data, but for phase III the differences between the experimental and calculated values were more significant. The thermal expansion coefficients indicated anisotropic behavior with large expansions along the *a* and *b* axes and a very small one along the *c* axis.

Molecular dynamics simulations were used to calculate a predicted melting point and examine some aspects of high-temperature solid-state phase transitions of AN crystals [212]. Simulations at various temperatures were performed for phase II AN.

The melting point of AN was predicted from calculations on this crystal structure, with voids introduced to eliminate superheating effects. The melting temperature was predicted by calculating the density and the nitrogen–nitrogen radial distribution functions as functions of temperature. The melting point was predicted to be in the range 445 ± 10 K, in excellent agreement with the experimental value of 442 K. The computed temperature dependencies of the density, diffusion, and viscosity coefficient for the molten liquid were in good agreement with experiments. The ammonium ions in the phase II structure are rotationally disordered at 400 K. At higher temperatures beginning at 530 K, the nitrate ions are essentially rotationally unhindered.

It is difficult to obtain sharp XRD Bragg peaks for nanocrystalline or amorphous energetic materials that usually give only diffuse halo patterns. Use of nano-AN would be a good method to increase the burning rates of AN-based propellants, but it is difficult to characterize the crystal structure of the small particles that contain only a few unit cells. The use of total scattering, in which both Bragg and diffuse components of the scattering are analyzed together, is a possibility for the study of this kind of problem, shown with AN as an example [213]. Theoretical-pair distribution functions of AN were calculated and compared with the experimental-pair distribution functions. The interpretation of the experimental-pair distribution functions may be similar to the Rietveld method.

Ab initio molecular dynamics simulations of the phase transitions and structural properties of AN at a pressure range of 5–60 GPa and temperature range of 250–400 K predicted two new phases: One corresponds to the experimentally observed phase IV', and the other was named AN-X [214]. The lattice strains play a significant role in the formation and stabilization of phase IV', providing an explanation for experimental observation of phase IV–IV' transition that appears only under non-hydrostatic pressure. Twelve O atoms neighboring the NH (N atom in ammonium cation) atom were selected as the reference system to clearly display the tangled rotation of the ammonium cation.

A first-principles evolutionary crystal structure search found a new crystal phase of AN [215, 216]. The calculated Raman spectra of this new phase were consistent with the experimental Raman spectrum that contained two peaks previously associated with a pressure-induced phase transition. The phase transition is predicted to occur at a pressure of 17 GPa, while the new phase was calculated to be lower in free energy than phase IV of AN (AN-IV) above a pressure of 10.83 GPa. The new phase has a monoclinic unit cell with the $P2_1/m$ space group symmetry (AN- $P2_1/m$). This new phase is similar to AN-IV except the ammonium molecules are oriented differently relative to the nitrate molecules. The calculated Raman spectrum of both AN- $P2_1/m$ and AN-IV as a function of pressure showed good agreement with experimental data up to 33 GPa.

2.3.11.6 Crystal Structure of Ammonium Nitrate Solid Solutions and Mixtures

A significant amount of effort has been devoted to modifying the crystal structure of AN by co-crystallizing or co-melting additives that prevent the large density change associated with phase transitions. One of the best examined additives is potassium nitrate [112, 217].

2.3.11.7 Crystal Deformation of Ammonium Nitrate

The plasticity and cold-flow extrusion behavior of AN extruded from a pressurized chamber through an orifice varies substantially with the phase transitions in different temperature regimes.

The flow stress of AN in an extrusion die indicated phase transformations, which were automatically recorded as breaks on the curves of extrusion pressures. Extrusions were made in a 39-kN press at a rate of displacement of the piston of 1 mm/min, with automatic recording of the pressure [218, 219]. Comparison of the data for AN with information on the plasticity of other substances showed that substances in the metastable state have a plasticity exceeding several times the plasticity of the stable forms. The plasticity of the separate modifications could be evaluated by comparing the flow stresses at various temperatures and pressures under isothermal and shifting temperature conditions. In the vicinity of the transition point, the plasticity of phase III $\gamma\text{-NH}_4\text{NO}_3$ is approximately 3.6 times greater than that of phase IV $\beta\text{-NH}_4\text{NO}_3$. At each phase transition, the ions in the crystal lattice have greater mobility while they are jostling for a new spatial arrangement, and the crystal is more deformable and extrudable.

2.3.12 Thermodynamic Properties of Ammonium Nitrate

2.3.12.1 Heat Capacity of Ammonium Nitrate

The heat capacity and the heat of fusion are needed for the design of industrial processes in which AN is melted either to be prilled or to be decomposed in the production of N_2O . The heat capacity of solid AN varies considerably depending on the phase composition of the sample. The values reported in the literature during the past 140 years vary considerably. Therefore, it was a welcome step when Dellien in 1982 reexamined and summarized literature values from eight different sources, summarized in Table 16, and derived a new set of data from his own DSC experiments, including studies on the effects of moisture and thermal history of the samples [220].

The heat capacities of AN were measured between 15 and 410 K for the stable and metastable phases by use of adiabatic-type and conduction-type calorimeters [222]. The phase transformations between stable phases, i.e., $\text{V} \leftrightarrow \text{IV}$, $\text{IV} \leftrightarrow \text{III}$, $\text{III} \leftrightarrow \text{II}$, and $\text{II} \leftrightarrow \text{I}$ and the metastable transition between phase IV and II, were all found to be of first-order type. The direct transition between V and II, which was realized only for a sample treated with a minute amount of surface active agent, was ascertained

to be a higher-order type. Heat and entropy of transition of five types of transitions were determined, and these results showed that the heat capacity data by Stephenson et al. [223] at low-temperature region are much more reliable than the values by Eichenauer [224]. The possibility of the existence of a seventh phase below 156K has been discussed, but this has been questioned by other investigators.

The heat capacity of AN and phase-stabilized AN with potassium nitrate, copper oxide, and nickel oxide was determined using a differential scanning calorimeter calibrated with sapphire and benzoic acid standards [225]. Heat capacity data were then compared with literature results, and those for the phase-stabilized AN were compared with earlier DSC results.

2.3.12.2 Enthalpy of Formation of Ammonium Nitrate

To obtain accurate data for the enthalpy of formation of crystalline AN by combustion calorimetry, one must make sure that corrections for the possible occurrence of undetected by-products of incomplete combustion are applied. The exact states of the respective samples of AN at the time of combustion must be totally in phase IV, and adsorbed water must be eliminated before the pellet is ignited.

The standard enthalpy of formation of AN in its stable reference state at 298.15K was derived from measurements of the energy of combustion of samples of hydrocarbon oil or polyethylene sheet in the presence of AN [221]. Under the conditions chosen, AN decomposed to $\text{N}_2(\text{G})$, $\text{O}_2(\text{G})$, and $\text{H}_2\text{O}(\text{L})$; the only significant by-product found was $\text{HNO}_3 \cdot n\text{H}_2\text{O}$. Special care was devoted to preparation of the NH_4NO_3 sam-

ple in its stable state (crystalline form IV), free of water. Combination of the resulting value of Δt_{H_0} with recent data on the enthalpies of solution and dilution of $\text{NH}_4\text{NO}_3(\text{cr, IV})$, together with key values from the CODATA compilation, gave $\Delta H_f^\circ(\text{NO}_3^-, \text{aq}) = -(206.81 \pm 0.41)\text{kJ/mol}$. The enthalpy of formation of crystalline AN in the phase IV condition was found from combustion calorimetric data with a hydrocarbon oil or polyethylene foil as $\Delta H_f^{298}(\text{NH}_4\text{NO}_3, \text{cr, IV}) = -(365.61 \pm 0.32)\text{kJ/mol}$.

The generally accepted tabulated value of ΔH_f^{298} of $\text{NH}_4\text{NO}_3(\text{c})$ is $-365.7 \pm 2.9\text{kJ/mol}$ ($-87.4 \pm 0.7\text{kcal/mol}$). See also [226].

The PEP data list shows ΔH_f^{298} AN as $-1090\text{cal/g} = -87.247\text{kcal/mol} = -365.04\text{kJ/mol}$ [227]. The molecular mass of AN is 80.043g/mol . This number is needed for conversion from mass-specific numbers to molar units and vice versa. Table 17 is a summary of published enthalpy-of-formation data for AN in its phase that is stable at 298 K.

Table 17: Standard enthalpy-of-formation data for ammonium nitrate.

Phase	Enthalpy of formation ΔH_f^{298} , SI units		Enthalpy of formation ΔH_f^{298} , other units		References
	kJ/mol	kJ/kg	kcal/mol	cal/g	
IV	-365.04	-4560	-87.247	-1090	[227]
	-365.6	-4567.0	-87.367	-1091.5	[228]
	-365.61 ± 0.32	-4567.7	-87.383	-1091.7	[221]

2.3.12.3 Enthalpy of Phase Changes of Ammonium Nitrate

The phase changes of AN are endothermic and exothermic and are reversible, depending on the direction in which the temperature change is taking place. Upon cooling, generally only one transition is observed, at 321 K (48°C). The enthalpies of phase changes rhombic to rhombohedral ($\text{III} \rightarrow \text{II}$) and β -rhombic to α -rhombic ($\text{IV} \rightarrow \text{III}$) vary substantially depending on sample history. Literature data vary widely. The $\text{II} \rightarrow \text{I}$ transition is well reproducible both as to size and temperature ($399\text{--}400\text{K}$ [$126\text{--}127^\circ\text{C}$]). One of the first multi-phase solids to be examined with newly developed DSC instrumentation in 1964 was AN [229].

In trying to consolidate sometimes contradictory data, Dellien [220] compiled the enthalpies of phase changes from numerous literature sources along with the heat capacity data and compared them with his own experimental results from DSC measurements. The results are summarized in Table 18.

The results of Stephenson, Bentz, and Stevenson [223] and Nagatani et al. [222] are in good agreement with each other with regard to both heat capacity and transition enthalpies. Their data were obtained using reliable experimental techniques.

Table 18: Enthalpy of phase changes of ammonium nitrate.

Phase transition	Temperature		Enthalpy of transition		References
	K	°C	kJ/mol	J/g

	399	126	4.594 ± 0.104	57.4 ± 1.3 (avg. of 17 runs)	[220]

2.3.12.4 Enthalpy of Fusion of Ammonium Nitrate

Any engineer who is tasked with designing a process that involves molten AN (prilling, nitrous oxide production) must have accurate data for the enthalpy of fusion (the heat of melting). The enthalpy of fusion is usually reported in the literature as the enthalpy of transition from phase I to the liquid phase, assuming that the solid crystals remained in the phase I regime long enough to equilibrate with the environment just prior to melting. The enthalpy of fusion of solid AN starting at room temperature (heating rapidly without allowing time for phase changes) would have to include the enthalpies of three solid–solid phase changes taking place above 298 K before the AN melts.

Enthalpy-of-fusion data reported in various literature sources are compiled in Table 19.

Table 19: Enthalpy of fusion of ammonium nitrate phase I.

Melting temperature		Enthalpy of fusion		Method	References
°C	K	kJ/mol	J/g		
170	443	6.363	79.5	DSC	[229]
169.3	442.45	6.403	80.0	Cryoscopy	[230]
		6.195 ± 0.264	77.4 ± 3.3	DSC, avg. of 13 runs	[220]

2.3.12.5 Enthalpy of Sublimation of Ammonium Nitrate

From the measured molecular weight of vapor over $\text{NH}_4\text{NO}_3(\text{c})$ by the simultaneous torsion-effusion/mass-loss method, the partial pressure of $\text{NH}_4\text{NO}_3(\text{g})$ was evaluated over the range 321–360 K [143]. The presence of the gaseous nitrate was verified by effusion-beam mass spectrometry (MS). Third-law calculations of the sublimation enthalpy of AN were made with estimated molecular constants, yielding an enthalpy of sublimation of $\Delta H_{298}^{\circ}(\text{subl}) = 87.4 \pm 8.3 \text{ kJ/mol}$ ($20.9 \pm 2 \text{ kcal/mol}$), as compared to a less reliable value of $97.07 \pm 12.55 \text{ kJ/mol}$ ($23.2 \pm 3 \text{ kcal/mol}$) derived from application of the second law of thermodynamics. If one trusts the third-law value, a first estimate for the enthalpy of formation of gaseous AN was $\Delta H_{298}^{\text{f}} \text{NH}_4\text{NO}_3(\text{G}) - 278.2 \pm 8.8 \text{ kJ/mol}$ ($-66.5 \pm 2.1 \text{ kcal/mol}$) when combined with the known $\Delta H_{298}^{\text{f}}$ value of crystalline NH_4NO_3 ($\Delta H_{298}^{\text{f}} \text{NH}_4\text{NO}_3(\text{C}) = -365.68 \pm 2.93 \text{ kJ/mol} = -87.4 \pm 0.7 \text{ kcal/mol}$). A later revision changed this to a different number, $\Delta H_{298}^{\text{fo}} \text{NH}_4\text{NO}_3(\text{G}) = -258.6 \pm 20.9 \text{ kJ/mol} = -61.8 \pm 5 \text{ kcal/mol}$ [231].

2.3.12.6 Enthalpy of Dissociation of Ammonium Nitrate

The standard free energy of dissociation of NH_4NO_3 (C, IV) to $\text{NH}_3(\text{G})$ and $\text{HNO}_3(\text{G})$ is $93.4 \pm 0.3 \text{ kJ/mol}$ [232]. Over the temperature range for which the crystalline phase IV is stable (-17 to 32°C), the temperature dependence of the dissociation constant is given to within $\pm 12\%$ by

$$\ln K_p = 118.87 - 24084/T - 6.025 \ln T$$

where T is the temperature in kelvin. For particles with radii less than $0.1 \mu\text{m}$, the Kelvin effect has a substantial effect on the vapor pressure and dissociation constant. However, particle size has little effect on the deliquescence point.

2.3.12.7 Enthalpy of Solution of Ammonium Nitrate

Enthalpy of Formation of Ammonium Nitrate Solutions

The difference between the enthalpy of formation of solid AN and the enthalpy of formation of AN solutions is the enthalpy of dissolution.

The heat of solution of AN for infinite dilution in water is $\Delta H_{\text{sol}}(\text{NH}_4\text{NO}_3, \text{cr, IV}, 4\text{H}_2\text{O}) = 25.544 \pm 30 \text{ kJ/mol}$ at 298.15 K , [233]. This heat of solution agreed well with data reported earlier where they had been reported as $\Delta H_{\text{sol}}(\text{NH}_4\text{NO}_3, \text{cr, IV}, 4\text{H}_2\text{O}) = 25.41 \text{ kJ/mol}$ [234]. The integral heat of solution forming a saturated solution at room temperature is about 16 kJ/mol . See also [226].

Table 20 gives the enthalpy of dissolution of AN in water compared with that of other high-energy oxidizers [235]. All of these salts cool off when dissolved in water, a fact that is used to advantage with AN in two-component instant ice packs for first aid for sports injuries.

Table 20: Standard enthalpy of dissolution of AN in water compared with that of other oxidizers.

Compound	Standard enthalpy of formation, kJ/mol		Enthalpy of dissolution, kJ/mol
	Crystalline solid	In solution at infinite dilution	
NH ₃ OHNO ₃	-366.5	-344.8	+22.5
NH ₄ NO ₃	-365.4	-339.9	+25.3
N ₂ H ₅ NO ₃	-246.9	-215.1	+31.8

Data source: [235]

Ammonium nitrate is reported to be appreciably soluble in aqueous and concentrated nitric acid; solutions of 50 mass-% AN in anhydrous nitric acid are commonly used in the manufacturing of explosives. Heat is evolved when AN is dissolved in 99.6% HNO₃, but heat is absorbed if AN is dissolved in water. The partial molal heat of solution of AN in HNO₃ is -27.2 kJ/mol (-6.5 kcal/mol) [236]. This heat of solution represents the heat evolved when a mol of the salt is dissolved in an infinitely large amount of the acid to form an infinitely dilute solution. At low concentrations, up to 0.15 mol AN/mol of HNO₃, the heat of solution is nearly proportional to the salt concentration (Table 21). Above 0.3 mol AN/mol HNO₃, it levels off at 20.9 kJ/mol (5 kcal/mol) of AN added. The solution process is thermoneutral if the HNO₃:H₂O molar ratio is about 1:1. In an ideal solution without thermal effects, the heat of solution is the same as the heat of fusion. In each case, the energy required to destroy the crystal lattice of the AN crystals is the same.

Table 21: Heat of solution of ammonium nitrate in anhydrous nitric acid.

Molality (298 K)	ΔH	
	kJ/mol	kcal/mol
0.2	-27.8	-6.65
1.0	-23.9	-5.72
1.5	-22.2	-5.30
2.3	-19.7	-4.70

2.3.12.8 Entropy of Ammonium Nitrate

The best value for the absolute entropy of AN at 298 K may be taken as 150.6 J mol⁻¹ K⁻¹ (36.0 cal mol⁻¹ °C⁻¹) [139]. The entropy of AN (phase IV) at 298.16 K was calculated as 151.08 J mol⁻¹ K⁻¹ (36.11 ± 0.05 cal °C⁻¹ mol⁻¹) [223].

2.4 Chemical Properties of Ammonium Nitrate

2.4.1 Stabilizer Additives to Prevent Phase Changes of Ammonium Nitrate

A significant amount of effort has been devoted to the search for stabilizing additives that will prevent the bothersome phase changes of AN, in particular the phase IV $\leftrightarrow$ phase III transition occurring at just above room temperature. Not all additives are equally effective for all phase changes. Some additives are effective only for shifting or eliminating one of the phase changes while the others remain unaffected. Phase-stabilized AN is known under the abbreviation PSAN.

At first we were not quite sure whether the chapter on stabilizing additives to prevent phase changes of AN should be placed under “Physical Properties” or “Chemical Properties.” There are no chemical reactions involved with the stabilizing mechanism. But because so many different chemicals have been evaluated, it felt appropriate to place this chapter under “Chemical Properties” instead of “Physical Properties.”

Three types of methods have been used to “stabilize” AN against phase transitions. One technique is to add dehydrating agents that remove the water that catalyzes the III $\leftrightarrow$ IV phase transition. The other methods use solid solution effects to alter the AN crystal lattice and its transition temperature. One approach is to use compounds that have identical orthorhombic crystal lattices and easily intersperse with AN. Phase stabilization is more effective if a solid solution and eutectic are formed. But there are exceptions: Although 5-aminotetrazole and AN form a solid solution and a eutectic, phase stabilization of AN is not achieved.

Efforts to stabilize AN against phase IV $\leftrightarrow$ phase III transitions have included combining it with additives such as potassium nitrate, zinc oxide, magnesium oxide, copper oxide, nickel oxide, potassium fluoride, potassium hexafluoroaluminate, and nickel oxide, as well as certain lithium, calcium, barium, and aluminum salts and other metal salts of the nitrate anion. Furthermore, organic compounds such as urea, ethylene diamine dinitrate, diethylene triaminetrinitrate, guanidinium nitrate, silicates, and melamine have also been investigated as AN stabilizers. None has proven entirely satisfactory. For instance, with regard to potassium nitrate, at least about 9 mass-%, generally about 10–15 mass-%, must be introduced into the AN crystal lattice to prevent transitions up to about 393 K (121°C). Crystal stability is achieved in many propellant compositions only at the expense of increased pressure exponents, reduced energy performance, reduced density, and increased smoke, all of which make the use of potassium nitrate undesirable as a phase stabilizer. Ammonium nitrate stabilized with CuO or with about 3 mass-% NiO has been reported to show little tendency to cake. However, such CuO- and NiO-containing compositions prevent environmental hazards, sacrifice energetic performance, and prevent aging and processing problems in energetic formulations.

Magnesium nitrate, potassium nitrate, potassium carbonate, ammonium dihydrogen phosphate, ammonium sulfate, and zinc nitrate were evaluated as stabilizing

agents for AN prills (fertilizer grade AN), but the stabilizers actually used were kept proprietary [237].

Most of AN is used as fertilizer, often in mixture with other fertilizers. Some of the fertilizer additives (ammonium sulfate, urea, calcium nitrate) to AN have beneficial side effects in that they also shift the phase-transition temperatures [238].

The kinetic constants and the enthalpy of phase transitions $\text{II} \leftrightarrow \text{I}$ of AN with and without addition of ammonium sulfate, magnesium nitrate, or ammonium polyphosphate were measured by DTA, and subsequently the samples were heated to incipient decomposition [239, 240]. See also [241].

In temperature regions with coexisting phases, Rietveld refinement has been used for quantitative phase analysis. The method yields lattice parameters and atom positions as well as intramolecular and intermolecular distances [190, 242]. The obtained data determined unambiguously the stability ranges and thermal expansion of the phases. They showed that the stability of the room temperature phase IV and that of phase II is extended to lower temperatures by adding the copper compound.

The solid-state reaction of AN and copper(II) oxide proceeds through an intermediate stage in the form of a solid solution of a diamminocopper(II) complex in the AN lattice, subsequently resulting in the formation of diamminocopper(II) dinitrate [243]. The crystallographic and kinetic aspects of the solid-state reaction of AN and copper(II) oxide were studied by *in situ* time- and temperature-resolved XRD. The kinetic profiles of the reaction were fitted by a nucleation and growth model. The rate of the reaction was found to increase as the dopant concentration decreased. The reaction resulted in an expansion of the tetragonal lattice of the AN along the base, resulting in a plausible pseudo-tetragonal-like structure.

Diammino copper (II) complexes were incorporated into the AN lattice to improve the phase behavior. The thermal expansion and the phase transitions of AN with diammino copper ("CuPSAN") contents corresponding to 7% CuO were measured with temperature-resolved XRD while the samples were heated in accordance with the temperature cycling programs 20/100/−70/100 and 20/143/−70/20 °C [244, 245]. A series of measurements were performed, while the samples were heated with the temperature cycling programs 20/100/−70/100 and 20/143/−70/20 °C. The series were evaluated by Rietveld refinement, yielding thermal expansion curves of the phases, which were identified by the known diffraction patterns. In temperature regions with coexisting phases, Rietveld refinement was used for quantitative phase composition analysis. The obtained data identified unambiguously the stability ranges and thermal expansion of the phases. It was shown that the stability of the room-temperature phase IV and of phase II can be extended to lower temperatures by selecting the correct stabilizer additives. Compared to pure AN, the elementary cell of phase V of CuPSAN approached a tetragonal structure like phase II.

A welcome side effect of the addition of stabilizers to AN is reduced hygroscopicity. However, moisture absorption remains a problem because water reduces the stabilizing effect of nickel oxide and other stabilizers.

2.4.1.1 Methods for Evaluation of Stabilizer Additives to Prevent Phase Changes of Ammonium Nitrate

The following methods are used for the study of phase changes occurring in AN either with or without the addition of phase stabilizers:

- Differential thermal analysis (DTA)
- Differential scanning calorimetry (DSC)
- Accelerating rate calorimetry (ARC)
- Dilatometry
- X-ray diffraction (XRD)

Dilatometric Measurement of Volume Changes

The effectiveness of stabilizing, anti-swelling additives can be measured in a dilatometer after repeated temperature cycling. A specially built dilatometer was filled with stabilized or unstabilized AN and topped off with mercury. The rise of the Hg column in a glass capillary during stepwise heating from 293 to 316 K (20 to 38 °C) gave a good indication of the effectiveness of the stabilizing agents. Results of tests on ten samples were reported [246].

Dilatometric investigations of natural and phase-stabilized AN have shown the beneficial effect of adding stabilizers [247–249].

A combination method of dilatometry and thermal analysis gives multiple answers when applied to phase changes occurring in AN [250]. With the aid of this apparatus it is possible to measure the temperature, the change in weight, and the dilatation of the sample, as well as the rate of the changes in enthalpy and weight and the velocity of dilatation (shrinking or swelling).

The swelling of propellant grains prepared with insufficiently stabilized AN, unstabilized AN, and PSAN is quite obvious when comparing the three cylindrical propellant samples in Figure 20 that went through a series of temperature cycling.

Figure 20: Example of swelling of ammonium nitrate-based propellant grains as a result of temperature cycling. *Left:* Cycled urea-stabilized AN; *Center:* Cycled AN propellant; *Right:* Cycled PSAN (ZnO-stabilized) propellant. Visual Examination Under the Microscope

Phase transitions $IV \leftrightarrow II$, $IV \leftrightarrow V$, and $II \leftrightarrow V$ of AN were examined through a polarizing microscope by using thin single crystals of various orientations [251]. In the transition $II \rightarrow IV$, a single crystal split itself into two kinds of crystals, in which the direction of the c -axis was common but the a - and b -axes were interchanged. A composite pattern appeared that was characteristic of the orientation of the initial crystal. The crystal composites had boundaries of $\{110\}$ planes, which may be twinning planes. The new phase grows in a specified direction in the mother crystal in conformity with a minimum strain postulate. The $IV \leftrightarrow V$ transitions were very similar to the $IV \leftrightarrow II$ transitions except for the appearance on occasion of a faint light/dark pattern of phase V. This pattern was probably due to the formation of micro twins. The $II \leftrightarrow V$ transitions occurred as a second-order transition in minute crystals within a temperature range of about 317 to 314 K (44 to 41 °C). The transformation was detected only by the same light/dark pattern of phase V in some crystals as in the case of the $IV \rightarrow V$ transition.

Quantitative conoscopy was used as a method to determine an optical orientation angle $2V\gamma = 86^\circ 15' (+)$ for the orthorhombic phase III and an angle $2V\alpha = 36^\circ 30' (-)$ for the orthorhombic phase IV [96]. Measuring the change in the optic axial angle allows one to monitor the transition from IV into II or II' as a function of time and temperature. At 349 K (76 °C), it took 50–100 d to stabilize the angle at 82° . The change occurred over an intermediate, metastable phase II' that persisted for the first 50 d and then underwent a secondary stabilization that took another 100–150 d to complete. The curve had a discontinuity at 50 d (refer to Figure 2, page 213, of de Saenz et al. [96]). The intermediate phase II' was obtained by annealing crystals in the stability range of phase III, resulting in crystals of tetragonal or lower symmetry. After some time, the crystals turned biaxial by annealing. Many discussions were carried on in the literature about the rather peculiar behavior of AN phase transitions. To a considerable amount, the speed and the extent of phase change depends on the history of samples with “memory.” The existence of nuclei of one phase persisting, after the transition, in the other phase (e.g., nuclei of III in IV) is part of this ongoing discussion.

Goniometric measurements were performed with similar results [252].

One of the plainly visible effects of phase changes during repeated temperature cycling of AN is that solid crystals or prills break apart into smaller particles and end up as a powder. The method of using particle-size analysis to examine the route of a phase transformation in a crystal slurry was tested, and results for the $IV \rightarrow III$ transition in aqueous slurries of AN crystals illustrated the viability of this technique [98].

Single crystals of phase IV AN shaped (ground or split) into thin foils show unusual elasticity in that they can be bent to nearly 180° without breaking. It was suggested that this elasticity of AN makes it difficult to comminute it by grinding and that grinding would best be done at lower temperatures at which the material is more brittle.

2.4.1.2 Inorganic Stabilizer Additives to Prevent Phase Changes of Ammonium Nitrate

Most of the stabilizing additives are nitrates of other cations. Some of the additives are ammonium salts with anions other than nitrate.

Metal Nitrate Additives

The most thoroughly investigated phase-stabilizing additive for AN is potassium nitrate, KNO_3 , abbreviated KN. Potassium nitrate has the advantage that it is less hygroscopic than AN, is readily available, is an oxidizer in its own right, and requires only 4–10 mass-% KN to achieve a noticeable improvement in either shifting or totally eliminating one of the phase changes.

The occurrence of a “metastable” transition at 323 K (50 °C) between modifications IV $\rightarrow$ II is associated with special drying of the sample or its immersion in a non-solvent. Prompt occurrence of the transition IV $\rightarrow$ III at 305 K (32 °C) would thus appear to depend on the presence of an aqueous phase. A surface film of saturated solution carried by the hygroscopic salt is most often responsible for its ready transition.

Potassium nitrate in solid solution in the AN modifications alters their temperature ranges of stability [102]. At 256 K (–16 °C), a 30% addition renders phase III completely stable, whereas phase IV becomes unstable with more than 8% of the added salt. Between these limits, equilibrium mixtures of III and IV can exist. However, with 10% or less of KNO_3 in suitable preparations, stabilization of phase III between 253 and 333 K (–20 and 60 °C) may be obtained, and claims have been made that as little as 1% KNO_3 is effective in phase stabilization. Stabilized AN has been made by mechanically mixing, co-crystallizing, or fusing a finely divided potassium salt with ammonium nitrate.

X-ray powder diagrams showed that solid solution formation by physical grinding takes place more easily between KNO_3 and phase III AN than phase IV AN [109]. The transition point is at 305.4 K (32.3 °C). Solid solution formation can take place by ion migration in the solid state and is accelerated by heating the mix to 323 K (50 °C). Mixed crystals containing 19.29% KNO_3 were crystallized from a saturated aqueous solution of 80 parts AN and 20 parts KNO_3 between 368 and 358 K (95 and 85 °C). The crystals turned out to be of the modification III of NH_4NO_3 , acicular, four faces of the (110) form, with interfacial angles nearly 86 and 94° and the angle between (110) and [110] faces being 94°. The refractive indices in the three different directions are $\alpha = 1.46$, $\beta = 1.54$, $\gamma = 1.60$.

It was suggested that surface solid solutions rich in KNO_3 would prevent surface nucleation with phase IV [253].

Ammonium nitrate was fused with 1 to 10% of $\text{Ce}(\text{NO}_3)_4 \cdot 6\text{H}_2\text{O}$ or $(\text{NH}_4)_2\text{Ce}(\text{NO}_3)_6$, and the phase-change retardation was evaluated by doing dilatometric, TGA, and XRD analyses [254]. The additives were not very effective.

A solid solution of AN containing 15 mass-% KN was obtained from the ternary system NH_4NO_3 - KNO_3 - H_2O [255]. The mixed crystals prepared by crystallization un-

der metastable condition were acicular with well-developed faces, while under unstable conditions, referred to as spinodal decomposition, rounded crystals could be obtained. It was found that the sphericity of the crystals was largely dependent on the interaction of hydrodynamics and growth of higher-ordered species of clusters in the system. To evaluate the AN (phase III) as an ingredient for explosive compositions, several formulations with such binders as TNT, acrylate elastomers, and silicone prepolymers were prepared and temperature-cycled. Dimensional stabilities of these compositions were confirmed with a thermal cycle test, dilatometer, and thermal and thermomechanical analyzer.

Modification of the room-temperature phase transition (IV $\rightarrow$ III) of AN has been attempted using a variety of potassium salts, including KNO_3 , KF, KCl, KI, K_2CO_3 , K_2SO_4 , KSCN, and $\text{K}_2\text{Cr}_2\text{O}_7$ [256]. No phase transition was observed when AN containing 1–2% by mass of these potassium salts was heated from room temperature (25 °C) upward in DTA and DSC scans, but the linear expansion due to phase transition was still observable in thermomechanical analysis (TMA) measurements. Complete arrest of the linear expansion could be achieved only when a higher concentration of the additive was used. Addition of potassium dichromate modified the phase as well as the decomposition pattern of AN.

Magnesium nitrate is not a desirable additive to AN, but the phase transitions in the AN/ $\text{Mg}(\text{NO}_3)_2$ system nevertheless have been mapped [257]. See also [114, 258].

Aluminum ion stabilizes phase IV of AN [259]. The objective of this work was to improve the stability of phase IV of AN by adding Al^{3+} cations to counteract the negative influence of contaminant cations such as Mg^{2+} . AN was doped, and NH_4^+ cations were replaced by Al^{3+} and Mg^{2+} by melting or co-crystallizing from aqueous solutions with $\text{Al}(\text{NO}_3)_3 \cdot 9\text{H}_2\text{O}$ and $\text{Mg}(\text{NO}_3)_2 \cdot 6\text{H}_2\text{O}$. The amount of additives was limited to 5 mass-%. XRD spectra at low temperatures confirmed the positive effect of Al^{3+} cations on the stability of phase IV of AN and the negative action of Mg^{2+} cations.

Dried samples of AN containing 1, 3, or 5 mol-% KNO_3 , RbNO_3 , or CsNO_3 were investigated with temperature-resolved XRD [260]. The samples were cycled repeatedly with two temperature programs from 203 to 373 K (–70 to 100 °C) and 203 to 423 K (–70 to 150 °C), respectively. DSC measurements were made for comparison. KNO_3 extended the stability range of phase III. The supercooling observed with the II $\rightarrow$ III and III $\rightarrow$ IV transitions was so severe that the phases III and IV could be skipped and the material changed directly from phase II to IV and III to V. RbNO_3 -doped AN behaved like moist AN. Phase III appeared on heating but was skipped on cooling, when the sample had been heated to 423 K. CsNO_3 stabilized phase II and V. No strong hysteresis or supercooling could be observed with CsNO_3 -stabilized AN.

The effects of KNO_3 on the phase transitions of solid AN were examined using *in situ* microscopic Raman spectroscopy [261]. Both the transition path and transition temperature of AN single particles (40–700 μm) depend on the KNO_3 mass percentage and the particle size. With the addition of KNO_3 , the IV $\rightarrow$ II transition, which appears at 325 K (52 °C) for pure AN, is replaced by the IV $\rightarrow$ III transition. The KNO_3 mass

percentage required for this change in the transition path increased with decreasing particle size, and the transition temperature decreased with increasing KNO_3 percentage. At a relatively high KNO_3 content ($\geq 7.4\%$), the $\text{KNO}_3/\text{NH}_4\text{NO}_3$ mixture underwent the IV $\rightarrow$ III transition under ambient temperatures, or even crystallized directly in phase III from droplets with a further increase in the mass percentage of KNO_3 .

Another phase-change stabilizer investigated is a mixture of potassium nitrate and disodium tetrahydrogen nitrilotris-(methylenephosphonate) [262].

Three-component inorganic additives can exert a synergistic effect, lowering the transition energy in AN phase changes. The additives were introduced into AN by isothermal co-crystallization from aqueous solutions. Phase stability in the system constituted by AN, potassium dichromate, and alkaline-earth metal (Mg, Ca, Sr) nitrates was measured by DTA at a heating rate of $3^\circ\text{C}/\text{min}$ [263]. The best results were obtained with mixtures containing magnesium nitrate, such as $\text{KNO}_3/\text{Mg}(\text{NO}_3)_2$ and $\text{KNO}_3/\text{K}_2\text{Cr}_2\text{O}_7/\text{Mg}(\text{NO}_3)_2$ [264]. It was expected that introduction of the additive(s) via isothermal crystallization from an aqueous solution would eliminate the IV $\rightarrow$ III phase transition and diminish to the maximum possible extent the activation energy of the thermal decomposition of AN. Introduction of magnesium nitrate leads to an increase in the activation energy of the decomposition of modified AN by 25 kJ/mol as compared with the pure substance (126 kJ/mol), and introduction of potassium nitrate and potassium dichromate leads to a decrease in E_a by 13 and 10 kJ/mol , respectively. For an addition of 4% total stabilizer, the optimal composition of a three-component stabilizer was as follows (mass fraction): $\text{Mg}(\text{NO}_3)_2$ 0.47, KNO_3 0.14, $\text{K}_2\text{Cr}_2\text{O}_7$ 0.39, or $\text{Mg}(\text{NO}_3)_2$ 0.44, KClO_4 0.21, $\text{K}_2\text{Cr}_2\text{O}_7$ 0.35.

Basic copper nitrate $[\text{Cu}(\text{NO}_3)_2 \cdot 3\text{Cu}(\text{OH})_2]$ in combination with AN has been investigated to improve the performance of gas-generating agents. In order to better understand the thermal behavior and stability of $\text{AN}/[\text{Cu}(\text{NO}_3)_2 \cdot 3\text{Cu}(\text{OH})_2]$ mixtures, samples prepared by two kinds of methods, with and without heat treatment, were analyzed using XRD to investigate the composition of samples, and DSC and TGA-DTAMS were used to investigate the thermal behavior and evolved gases [265]. It was found that $[\text{Cu}(\text{NH}_3)_2](\text{NO}_3)_2$ was formed in the sample with thermal treatment. The samples with and without heating exhibited different decomposition behavior. The residual AN and the amount of $[\text{Cu}(\text{NH}_3)_2](\text{NO}_3)_2$ in the mixture may affect the decomposition behavior.

KNO_3 -stabilized AN intended to be used in solid gas generants has been coated with organic polymers to reduce its hygroscopicity [266]. The thermal stability of coated AN/KN is not much different from uncoated stabilized AN/KN [267–269].

Dinitramide Additives

A deviation from the historical trend to use nitrates of different cations to interrupt the regularity of the AN crystal lattice is the application of metal dinitramidates (also ADN) and the dinitramide anion as stabilizers [270, 271]. This not only stabilizes the AN but it also improves its performance as a rocket propellant oxidizer. Ammonium nitrate is

phase-stabilized against phase IV $\leftrightarrow$ phase III transitions and the undesired volume changes associated with that phase change by the inclusion of an effective amount of at least one metal dinitramide salt having the formula $M[N(NO_2)_2]_n$ wherein M is a metal cation and n is 1, 2, or 3. Metals claimed in the patent include a good part of the periodic table of elements, in particular lithium, cerium, potassium, zinc, and lanthanide elements.

Another application of potassium dinitramide (KDN) would be as a stabilizer for AN. While KNO_3 has been used for decades as a stabilizer for AN in solid-propellant and gas-generant formulations, the disadvantage of KNO_3 is that it reduces the performance of AN as a rocket propellant. KDN, however, more than compensates for the performance loss due to the introduction of the potassium [272, 273].

AN phase transitions leading to volume change can be overcome by the use of phase stabilizers. Unfortunately, most of the phase stabilizers used to prepare PSAN are non-energetic, and the overall energy content of the formulation is reduced to some extent. Using KDN as a stabilizing additive makes a PSAN with improved energy content. A DSC study of KDN/AN compositions evaluated KDN concentrations in the range of 0.2 to 5% (by weight). PSAN samples containing 0.2, 0.5, 1, 3, and 5% KDN were prepared, and their thermal properties were examined using DSC. The results showed that at concentrations above 3%, KDN has a good phase-stabilization effect on AN [274, 275]. An overlay of the DSC curves with increasing KDN additions (Figure 21) shows the complete disappearance of the phase transition at 327 K (54 °C).

Figure 21: Overlay of DSC curves of AN with increasing KDN additions. (Reprinted and modified from [274], with permission granted by Dr. Santhosh 8 February 2021.)

In ADN-AN mixtures with different mol ratios that were analyzed using DSC, the maximum melting endotherm was obtained for a mixture with mol fraction $\chi_{\text{ADN}} = 0.71$, demonstrating that the eutectic point (marked with E in Figure 22) is close to this value [276].

Binary ADN/AN phase diagram calculations were performed using a basic model based on ideal ionic liquid and pure non-miscible solid phases, and they were compared to the experimental-phase diagram determined by DSC analyses of 24 prepared ADN/AN compositions [277]. Both oxidants have their ammonium $[\text{NH}_4^+]$ cations in common and possess anions composed of nothing other than oxygen and nitrogen atoms. These results were then compared to estimated binary phase diagrams of AP/ADN and AP/AN systems. Table 22 summarizes the enthalpy of fusion and melting points of the pure compounds used as input data for this study. The estimated eutectic point of the AN/ADN mixture is at 328.0 K (54.9°C) for a predicted mol fraction of ADN $\chi_{\text{ADN}} = 0.43$, but the experimental eutectic was more at $\chi_{\text{ADN}} = 0.6$.

Figure 22: DSC thermograms of AN/ADN mixtures with increasing ADN concentrations at a heating rate of 2°C/min (Reprinted and modified from [277] with permission from Dr. X. Secordel 26 May 2020.)

Table 22: Enthalpy of fusion and melting points of AN, ADN, and AP.

	ΔH_{fus}		T_{fus}	
	kJ/mol	kcal/mol	K	°C
AN	6.11	1.46	442.7	169.6
ADN	17.62	4.21	366.0	92.9
AP	29.30	7.00	513.1	240

Data source: [277]

As shown in Figure 22, from $\chi_{\text{ADN}} = 0.00$ at the top thermogram, two clear endothermic peaks appear close to 325 and 399 K (52 and 126 °C), corresponding to the IV $\rightarrow$ II and II $\rightarrow$ I solid-solid transitions, respectively [277]. The II $\rightarrow$ I transition peak integrated intensity decreases progressively with the increasing amount of ADN (top to bottom) and vanishes for $\chi_{\text{ADN}} = 0.217$. The new peak (E) close to 333 K (60 °C) is typical of the eutectic transition at constant temperature.

A very detailed review of various methods and additives for phase stabilization of AN included additional data on the effectiveness of KDN as a stabilizing additive [278]. With the addition of only 5% KDN, AN can be phase stabilized, and the KDN addition to AN crystals increased the energy capacity of AN significantly. The phase transition of AN at 330.79 K (57.64 °C) was completely removed by the addition of 3% of KDN. For AN/KDN propellant systems, a maximum of 30% KDN can be added to AN. The reason for this limitation lies in the decomposition mechanism of KDN.

Metal Ammino Complexes as Additives

Ammino complexes of Ni, Cu, or Zn stabilize phase IV, while KNO_3 stabilizes phase III.

Cobalt(II)hexammino nitrate is one of the several ammino complexes evaluated as stabilizers for AN [279]. Ammino complexes of Co(II), Ni(II), and Zn were claimed and patented as stabilizers [280]. The metals are added to molten AN in the form of hydroxides or carbonate [281, 282]. The additives are melted with AN, and the melt is sprayed into a prilling tower to obtain spherical particles. NiO and ZnO were also claimed as stabilizers. In another approach, copper(II) oxide or nickel oxide is melted with one-tenth of the AN to be treated while bubbling ammonia through the melt at 383–443 K (110–170 °C) to form the ammino complexes, followed by adding the remaining nine-tenths of the AN to the melt and prilling [283].

AN samples stabilized with copper(II) diammino and copper(II) tetrammino complexes were stored for 4–5 years and re-analyzed using DTA and dilatometry [248]. Samples stabilized with copper(II) diammino complexes showed little or no tendency to agglomeration, and DTA did not reveal any III/IV phase changes below 323 K (50 °C). Copper(II) tetrammino complexes were equally effective. The effectiveness of either additive depends on the moisture content of the samples.

The volume increase due to the phase transition $\text{IV} \leftrightarrow \text{III}$ of AN at 305 K (32 °C) is reduced by incorporating the diammino complexes of nickel, copper, or zinc into the lattice, as shown by dilatometric measurements [249]. The transition temperatures are raised above 323 K (50 °C) by the nickel and copper ammino complexes. The zinc complex is less effective, depending on the water content of the samples.

Ammonium nitrate doped with copper diammino dinitrate and stored for 10 years was reinvestigated by DTA and TMA [284]. The phase transitions $\text{IV} \leftrightarrow \text{II}$ and $\text{IV} \leftrightarrow \text{III}$, which are of concern for the practical use, still occur above 323 K (50 °C), but they are less likely to take place during storage in a military underground magazine that rarely gets that warm. Despite moisture contents between 0.4 and 1.4%, no caking was observed.

Zinc diammino nitrate in AN can be formed by melting a 1:3 mixture of ZnO and AN, removing the water of reaction by purging with a dry gas, adjusting the ammonia balance by bubbling ammonia through the melt, and adding the product to molten AN to obtain a final composition with about 1–4 wt-% Zn [285]. Propellants prepared with this type of PSAN did not suffer swelling when temperature cycled. However, in wet PSAN, the zinc diammino complex may hydrolyze and lose ammonia and form an AN-insoluble hydroxide.

NH_4NO_3 , $\text{NH}_4\text{NO}_3/\text{KNO}_3$, $\text{NH}_4\text{NO}_3/\text{CsNO}_3$, and NH_4NO_3 with nickel(II) diammino nitrate, copper(II) diammino nitrate, and zinc diammino nitrate were investigated using XRD for an unambiguous determination of their phase properties [286]. The samples were cycled stepwise with a temperature program from 298 to 373 K (20 to 100 °C), cooled to 203 K (–70 °C), and heated back to 373 K (100 °C). Diffraction patterns were measured after each step every 2.5° increment. The measurements resulted in information about the phases present and their phase transitions. The ingredients are readily available for the development of propellants in bulk quantities of metric tons with particle size of 20–500 μm .

Metal Oxide Additives

The action mechanism of metal oxides is different from that of nitrates or dinitramides. Due to the acidic hydrolysis of AN, some of the metal oxides are superficially converted to nitrates and interact with the crystal lattice. In some cases, the metal oxides dissolve in molten AN if some excess ammonia is bubbled through the melt, converting the insoluble metal oxides to soluble ammino complexes. Because metal oxides are basically insoluble in AN, it is important to use finely divided metal oxides in the smallest particle size available. This is one example where nano materials promise to bring improved properties.

Most of the stabilizer work in AN has been done with copper(II) oxide, but copper(I) oxide has also been tested to see whether Cu(I) will become oxidized to Cu(II) under conditions of the AN melt [287]. This can be done by electron paramagnetic resonance measurements.

The phase changes of AN doped with small amounts of NiO or CuO have been studied using XRD and neutron diffraction at temperatures from 80 to 423 K [288]. AN with metal-oxide additives, which are believed to form complexes, exists as a solid solution. Phase IV was stable down to 140 K in the NiO-doped samples and to 210 K in the CuO-doped sample. While most previous studies looked just at the overall volume change, it has now been noted that the crystal growth (shrinkage) is not uniform in all directions of the crystal lattice. The thermal expansion of phase IV is extremely anisotropic, with the *b*-axis expanding rapidly with increasing temperature while the *a*-axis contracts slightly. At higher temperatures the doped samples transformed directly from phase IV to phase II, bypassing phase III, starting at about 328 K. Based on new data, the structure of phase II, which is disordered, was refined and has now been assigned to space group *P4/mbm*. The structure of phase III contains hydrogen-bonded chains parallel to the *b*-axis.

The stabilizing effect of ZnO was measured using temperature-programmed energy-dispersive XRD [289].

Metallurgical wastes are often used in the production of fertilizers enriched with vital essential elements, including zinc. Besides zinc oxide, they may contain iron, calcium, and magnesium oxides. Zinc oxide reacts with AN, forming water-soluble zinc nitrate hexahydrate, $\text{Zn}(\text{NO}_3)_2 \cdot 6\text{H}_2\text{O}$, and a less water-soluble compound, which has been characterized as complex zinc nitrate hydroxide hydrate, $\text{Zn}_5(\text{NO}_3)_2(\text{OH})_8 \cdot 2\text{H}_2\text{O}$ [290].

Rare-earth oxides, namely Y_2O_3 , Nd_2O_3 , La_2O_3 , and CeO_2 , were evaluated as phase stabilizers for AN in comparison with CuO and NiO [291]. DTA studies established the effectiveness in overcoming the problem of IV $\rightarrow$ III transition occurring at 32 °C. A new endotherm was observed for PSAN incorporating 4% rare-earth oxides in the temperature range of 55–60 °C, as reported by others for CuO-stabilized and NiO-stabilized PSAN. Incorporation of Y_2O_3 or CeO_2 can reduce the moisture susceptibility of AN. DSC data confirmed the phase stabilization of AN containing rare-earth oxides with respect to phase IV–III transition at 32 °C. XRD patterns provided evidence in support of a change in the crystal structure of AN doped with Y_2O_3 or CeO_2 , which may be the cause of their effectiveness as phase stabilizers.

Ammonium nitrate that was phase-stabilized with copper(II) diammino dinitrate was cycled between 203 and 373 K (–70 and 100 °C) in steps of 10 °C, with diffraction patterns measured after each step [292, 293]. The measured XRD series were used for phase identification and for Rietveld analysis, which provided the elementary cell parameters and quantitative phase analysis for temperature regions with coexisting phases. Expansion coefficients were calculated from the elementary cell dimensional data. During cycling, the phases II and IV were observed exclusively. Phase IV changed on heating into phase II, which on cooling reconverted into phase IV. With a CuO concentration of 3 mass-% the transitions were complete, whereas with 5 and 7 mass-% CuO, only partial reconversion was observed into phase IV at essentially

lowered transition temperatures, with parts of the sample remaining until 203 K (-70°C) in phase II or the similar phase V, which are not easily distinguishable.

Copper phase-stabilized AN (Cu-PSAN) was prepared by the incorporation of copper(II) oxide into the AN crystal lattice by a melt process. The phase transitions of AN and dimensional changes occurring during this phase-stabilization process, and crystallographic aspects of the solid-state reaction between AN and CuO and thermal behavior of phase-stabilized AN were measured. It was found that solid-state reactions occurred by an intermediate solid solution formation [294]. Lattice parameters and unit cell volume as a function of temperature were derived from XRD patterns. They showed a non-linear and anisotropic behavior with increasing temperature, such as lattice expansion along the *b*-axis and contraction along the *a*- and *c*-axes. The unit cell volume increased with temperature.

Earlier PSAN-based propellant formulations used a PSAN containing 3.5% nickel oxide. Unfortunately, after some promising formulations had been developed, NiO was identified as a potential carcinogen. All subsequent formulations have contained 3% zinc oxide PSAN instead of 3.5% NiO PSAN.

Anatase-brookite mixed-phase TiO_2 nanoparticles ($\sim 10\text{ nm}$) were used as catalyst to enhance the reactivity of AN [295]. The activation energies required for the decomposition reactions, computed by differential and non-linear integral isoconversional methods, were used to compare the catalytic activity. Presumably, the removal of NH_3 and H_2O , known inhibitors of AN decomposition reaction due to the surface reactions on the active surface of TiO_2 , changes the decomposition pathway and thereby the reactivity.

CuO has been used as a stabilizer for AN [296]. A DSC thermogram of CuO-stabilized AN is shown in Figure 23. This thermogram should be compared to that of pure AN under identical conditions, shown in Figure 24. When comparing the two thermograms, it is obvious that several of the phase changes were suppressed by adding CuO.

An analysis of the thermal decomposition mechanism of AN and copper(II) oxide (CuO) mixtures using DSC and evolved gas analysis based on TGA-DTA-MS was carried out, and decomposition behavior was observed using a hot stage with a camera containing a charged-coupled device [297]. DSC results showed that the AN/CuO mixture had a higher exothermic onset temperature than pure AN and that CuO did not promote the decomposition of AN. From TGA-DTA-MS results, the endothermic reaction of AN/CuO mixture started after the AN melting point of 442 K and resulted in the evolution of H_2O . At approximately 500 K or above, the AN/CuO mixture generated significant quantities of N_2 and H_2O , and an exothermic reaction began to offset the endothermic processes. Above 510 K, the AN/CuO mixture began to evolve NO_2 . Around 493 K, molten AN/CuO changed to a deep blue color because of the presence of a copper(II) amine complex.

Ammonium nitrate was co-crystallized along with copper(II) oxide, titanium dioxide, or lithium fluoride as candidate stabilizers, and thermal kinetic constants for the

Figure 23: DSC thermogram of phase-stabilized AN with CuO. (Reprinted and modified from [296], by permission of the publisher Taylor Francis Ltd, <http://www.tandfonline.com>).

Figure 24: DSC thermogram of pure ammonium nitrate. (Reprinted and modified from [277] with permission from Dr. X. Secordel 26 May 2020.)

decomposition reactions of the samples were calculated by model-free and model-fitting methods [298]. The results of the model-fitting method showed that the decomposition mechanism for all samples was a contracting cylinder mechanism. The phase behavior of the obtained samples was evaluated by DSC, and structural properties were determined by XRD. The results indicated that copper oxide modifies the phase-transition behavior and can catalyze AN decomposition, whereas LiF inhibits AN decomposition.

Titanium dioxide (TiO_2) nanocatalyst with an average particle size of 10 nm was synthesized by a sol-gel method using titanium alkoxide as precursor, and the catalytic effect of TiO_2 nanocatalysts on the solid-state thermal decomposition reaction of AN and non-aluminized AN/hydroxyl-terminated polybutadiene (HTPB) propellant was evaluated [299]. To quantify the effectiveness of the TiO_2 nanocatalyst, the thermal decomposition kinetic constants for the catalytic and non-catalytic decomposition of AN and AN propellant samples were computed and compared by using a non-linear integral isoconversional method. The catalytic influence of TiO_2 was evident from the lowering of the activation energy for the catalyzed decomposition reactions. Apparently, the TiO_2 nanocatalysts provide Lewis acid and/or active metal sites, facilitating the removal of AN dissociation products NH_3 and HNO_3 and thereby enhancing the rate of decomposition.

Potassium Fluoride Stabilizer

A PSAN mixed crystal structure can be produced by the addition of potassium fluoride (KF) [300, 301]. Thus, the undesirable abrupt expansion and contraction of AN in the temperature range of use in rocket motor propellants and explosives is eliminated. The stabilized AN is made by the addition of between 3 and 5% and preferably about 3.5 mass-% KF to the AN by a non-hazardous aqueous solution method. The aqueous solution method is safer than the melting method described in prior art patents. Propellants made with AN containing only 2% KF were not effectively stabilized, but an Omax-601-type compression-molded propellant formulation containing AN stabilized with 3.5% KF and also containing Milori blue (ferric ferro ammonium ferrocyanide) and bonded with HTPB suffered only 0.87% volume change after 30 temperature cycles, whereas a grain prepared with unstabilized AN had swollen by 3.2%.

Samples of AN containing 4 mass-% KF were investigated during cycling the material between 203 and 353 K (−70 and 80 °C) [302–304]. The incorporation of 2–4% KF into the AN lattice extended the stability range of phase III to lower temperatures. The results differed in dry and humid samples. In dry samples, phase III changed directly into phase V on cooling at temperatures between 263 and 208 K (−10 and −65 °C). The transitions were not complete in dry samples. In humid samples, the transition into phase V was complete and occurred at higher temperatures between 278 and 263 K (5 and −10 °C). In this case, phase IV could not be excluded reliably. It was suggested that the differences can be explained by a retarded nucleation of phase V in the dry

samples. On heating, the transition V $\rightarrow$ IV occurred in all samples at temperatures slightly above 273 K (0 °C), followed by the transition IV $\rightarrow$ III at 303–308 K (30–35 °C). Due to the extended stability range of phase III, a direct transition V $\rightarrow$ III could then be observed in the dry samples.

Thermal analysis by DSC of crystallized AN prepared from an aqueous solution containing 1 mass-% KF and heated from room temperature to 573 K (300 °C) showed the disappearance of the phase transformation that normally appears at 305 K (32 °C) [305]. Phase changes appeared only at 364.7, 395.9, and 435.9 K (91.6, 122.76, and 162.82 °C), even after the AN was stored under natural conditions for 75 d or was exposed to heating at elevated temperature and cooling to room temperature several times. Potassium fluoride also accelerated the thermal decomposition of AN.

Other Inorganic Stabilizing Additives

The main objective for stabilizing additives is to prevent or suppress the unwanted phase changes. Other additives may delay the thermal decomposition of AN [306].

Significant improvement in the dimensional stability of AN was achieved using 0.05 mass-% FeSO₄ [307]. After being subjected to 23 temperature cycles, an AN sample containing 1% FeSO₄ did not show any volume change, whereas an unstabilized sample had swollen by 50% of its original volume.

The use of ammonium sulfate (AS) as a stabilizer may not be the best choice for AN as a rocket propellant, but it would be very convenient for stabilizing AN that is to be used as a fertilizer, since AN/AS mixtures are commonly used as fertilizers anyway. Based on DTA and XRD investigations of the changes induced in the phase transitions of AN by the addition of AS (and water) and by repeated heating and cooling cycles going through the NH₄NO₃(IV) $\leftrightarrow$ NH₄NO₃(III) phase transition point, AS is not a very effective stabilizer [308].

A variety of potassium salts have been tested in an effort to prevent or at least shift the IV $\leftrightarrow$ III phase transformation of AN [256]. The salts tested include KF, KCl, KI, KNO₃, K₂CO₃, K₂SO₄, KSCN, and K₂Cr₂O₇, typically in concentrations of 1–2 mass-% in AN. KF was a better stabilizer than KNO₃. The samples were analyzed by DSC, DTA, dilatometer, and XRD. DSC and DTA thermograms did not show any phase-change endo/exotherms, but the linear expansion due to phase transition was still observable in the dilatometer. That undesirable phase change could be avoided only if a higher concentration of the additive was used. In thermal cycling experiments in which the samples were cycled between 193 and 373 K (–80 to 100 °C), the phase change could be suppressed only with fairly high additive concentrations (6–8%). Potassium dichromate showed a dual effect: It modified the phase transition and changed the thermal stability of AN. An unstabilized AN pellet would typically expand in the dilatometer by 6.6% linearly when heated from room temperature to 403 K (130 °C).

Stabilized AN was prepared by adding more than 20 different inorganic additives at a dosage of ~1 mass-%, and the effects of these additives on AN polymorphs were studied using DSC [309]. The results showed that potassium salts prevented the tran-

sition of IV $\rightarrow$ III effectively; oxide, $\text{Cu}(\text{NO}_3)_2$, $(\text{NH}_4)_2\text{SO}_4$, and MgSO_4 prevented the transition of III $\rightarrow$ II; and the composite of KCl and ZnO prevented both transitions of IV $\rightarrow$ III and III $\rightarrow$ II simultaneously. The effects of inorganic additives on AN phase transition are the co-active results of such factors as anion and cation radius and their matching, ion substitution, the formation of solid solutions, solubility, charge distribution, and ion stereo structure.

2.4.1.3 Organic Stabilizer Additives to Prevent Phase Changes of Ammonium Nitrate

The addition of 0.03–1 mass-% urea to dry AN can reduce its rate of decomposition at 473 and 498 K (200 and 225 °C) [310–312]. The same results were obtained by adding urea to a 60–70% AN solution and co-crystallizing before drying. The pH of a 10% solution of a sample taken from NH_4NO_3 heated for 1 h at 473 K was 3.15; after 0.5 h at 498 K, it was 2.09 due to increasing acid formation. The corresponding values of the pH of stabilized NH_4NO_3 containing 0.1–1 mass-% urea were 6.55–6.6. Urea and NH_4NO_3 stabilized each other only at small urea additions because the addition of 2–5 mass-% urea lowered the stability of the system. This was attributed to the instability of urea itself. The pH of samples taken from AN/urea mixtures containing 1.0 mass-% urea and kept at 498 K (225 °C) and dissolved in water increased during the first 5 min and then remained constant, whereas that of a control experiment, without an inhibitor, continued to decrease. Besides urea, the best inhibitor was Zn, the activity of which has been ascribed to the complex $[\text{Zn}(\text{NH}_3)_4](\text{NO}_3)_2$.

The substance *n*-octadecylamine, $\text{C}_{18}\text{H}_{37}\text{NH}_2$, has a retarding effect on the IV $\rightarrow$ II and IV $\rightarrow$ V phase transitions and wet sintering of AN [313].

Aliphatic amines influence the kinetics of the IV $\leftrightarrow$ III polymorphic transformation of AN [314]. Surfactants influence the kinetics of the IV $\leftrightarrow$ III polymorphic transformation of AN [315].

AN phase stabilization is typically accomplished by introducing another substance into the AN crystal structure. Salts containing ions larger or smaller than either ammonium or nitrate ions have been used. Because the U.S. military has decided not to use nickel or copper phase-stabilizing agents, the Air Force Research Laboratory has been looking for alternative materials for phase-stabilizing AN for use in solid propellants [316, 317]. Use of *N,N,N',N'*-tetramethyl-hexane-1,6-diamine appears to solve many AN problems such as phase changes, propellant grain growth during temperature cycling, moisture interference during curing, and caking in environments of 50% relative humidity. Interference of propellant cure using isocyanate curatives commonly occurs due to moisture content in the AN. Coating of AN particles with tetramethylhexane diamine was accomplished by bubbling nitrogen through the diamine and carrying the vapor through a bed of AN particles supported by a glass filter element. The AN particles had been carefully dried and screened, providing an initial free-flowing powder. Ammonia evolution was tracked by a Nicolet Impact 400 Fourier transform spectrometer. When ammonia evolution became undetectable, the coated AN was found to have increased in weight by

1.03%. The vapor pressure of the tetramethylhexamine was low, and the rate of mass transport was slow. Since the amount of tetramethyl hexane diamine needed to halt the ammonia replacement process was fairly large, the layer of tetramethylhexane diamine dinitrate salt was much thicker than a unimolecular layer. This indicated that some migration of material at the particle surfaces occurred during the diamine treatment of AN. DSC scanning of the tetramethylhexane diamine-coated AN provided a surprise: The typical 325 K (52°C) phase IV to phase II crystal transition was moved to about 344 K (71°C). Absence of the 325 K (52°C) phase change for the elevated-temperature-coated AN attested to completeness of AN particle coating. In another experiment, AN was coated at temperatures above 325 K (52°C). Elevated-temperature-coated AN particles did not exhibit caking activity over a 16-month period in a controlled 50% relative humidity environment. Free-flowing powder stored long term at 50% humidity demonstrated that the tetramethyl hexane diamine coating process totally eliminated AN phase III.

Some organic additives have a stabilizing effect on AN crystal phase changes that is indicated by decreasing the thermal effect of crystal transformation as measured by DSC [318]. These additives, including sawdust, cotton fiber, phosphonic acid, potassium chloride, and potassium bichromate, inhibited or shifted the phase change, but they also accelerated the thermal decomposition of AN at higher temperatures, lowered the exothermic temperature, and caused the energy release to occur more abruptly.

Ammonium nitrate that is intended to be used as an oxidizer in airbag inflator gas generants cannot be stabilized with KNO_3 because the gas generant would then no longer be smokeless. Also, sulfur-containing or halogen-containing stabilizers had to be eliminated for toxicity reasons. The search for stabilizers was therefore extended to organic compounds as stabilizers for AN [319, 320].

A polyvinylpyrrolidone (PVP)-AN glass provides both phase and thermal stabilization of AN [321]. PVP is capable of separating AN into its ions through an ion-dipole interaction. The ions remain separated below the glass transition temperature (T_g) of PVP (~433 K [~160°C]), which is confirmed by the disappearance of the solid-solid phase transitions associated with AN. Above the T_g , AN ions recombine, giving rise to a fast exothermic reaction suitable for rocket propellants. The material was then characterized by DSC, TGA, and FTIR.

The phase stabilization of AN with minor additions of organic substances with crystallographic parameters close to those of AN has been studied [322]. In order to restrain or prevent AN phase transitions, six types of polymers were added to AN, and the effects of polymers on AN phase transitions were studied using DSC [323]. The results showed that sodium *p*-ethylenebenzenesulfonate-acrylic acid polymer had little effect on AN phase transitions, whereas sodium *p*-ethylenebenzenesulfonate-dodecyl acrylate polymer prevented the transition of IV $\rightarrow$ III effectively. In addition, sodium *p*-ethylenebenzenesulfonate polymer, dodecyl acrylate, sodium *p*-ethylenebenzenesulfonate-*N,N*-dimethyldiallyl ammonium chloride polymer,

and sodium *p*-ethylenebenzenesulfonate-dodecyl acrylate-*N,N*-dimethyldiallyl ammonium chloride polymer effectively prevented the III $\rightarrow$ II transition. The mechanism of polymer phase stabilization of AN may be that polymers strengthen the hydrogen-bond network and impede the free rotation of NO_3^- .

The effect of the potassium salt of polyacrylic acid on phase stabilization of AN was tested using DSC and XRD [324]. The results showed that when the amount of the additive was more than 2.0%, it could prevent IV $\rightarrow$ III phase transitions of AN and raise the III $\rightarrow$ II phase-transition temperature to 110 °C. There are two effects when the potassium salt of polyacrylic acid is used as phase stabilizer: one is the replacement of ammonium ions in AN by potassium cations, and the other is a thin polymer coating on the surface.

DSC results showed that organic compounds and potassium salts of organic compounds can have an effect on the phase-transition behavior of AN [325]. The samples were further analyzed using IR and XRD spectra. The influence of additives on the phase transition of AN may occur through the polar groups that are involved in intermolecular interactions of orbital and electrostatic types that form new hydrogen bonds. AN existed in only one phase in the temperature range from 303 to 373 K (30 to 100 °C) when a potassium salt of organic compounds was added. However, with organic compounds, the III $\rightarrow$ II phase transition was changed. Compacted samples of AN containing potassium salts of organic compounds exhibited better stability than AN containing organic compounds to multiple cyclic changes within a temperature range.

The addition of amino acids to AN changes the temperatures of the solid-state phase transitions [326]. AN was combined with various amino acids in equimolar ratios; the phase transitions of the resulting mixtures were studied using DSC, *in situ* Raman spectroscopy, and XRD; and the predicted stabilities of various molecular structures were assessed via quantum calculations. DSC and Raman results indicated that *l*-glycine and *l*-alanine inhibited the solid-state phase transitions of AN. Both XRD and calculation results suggest that AN reacts with these amino acids to form nitrate salts and that clusters are also generated by interactions between these compounds.

2.4.2 Additives to Improve Thermal Stability of Ammonium Nitrate

Urea has been added to AN to prevent phase changes and to improve thermal stability. Urea/AN mixtures are also used as fertilizers.

The thermal decomposition temperature and surface morphology of AN/urea samples were investigated using DSC and SEM [327]. The results indicated that urea can substantially increase the thermal stability of AN (the largest exothermic peak was shifted by more than 100 °C) and reduce its thermal sensitivity.

The thermal stability and thermal decomposition behavior of AN and its mixtures with 1–20% of ammonium dihydrogen phosphate (ADP) were investigated using DSC-TGA, DSC-TGA-quadrupole mass spectroscopy, and TGA-FTIR [328]. Experimental re-

sults showed that the AN-ADP mixtures had higher onset of decomposition temperatures, narrower reaction temperature ranges, and lower enthalpy values than pure AN. Onset temperatures for AN-ADP mixtures with 1, 5, 10, 15 and 20 mass-% ADP were 539.4, 539.9, 541.0, 543.3, and 544.6 K (266.3, 266.8, 267.9, 270.2, and 271.5°C), respectively. The main evolved decomposition gases of pure AN were NH_3 , H_2O , NO , N_2O , NO_2 , and HNO_3 , while the major gaseous products of the AN mixture with ADP were NH_3 , H_2O , NO , N_2O , and NO_2 . A proposed decomposition mechanism of an AN-ADP mixture and the inhibition mechanism of ADP was discussed. It was concluded that ADP is an effective inhibitor for AN and that its thermal stability can be improved by this method.

2.4.3 Reactions of Ammonium Nitrate

One of the most important reactions of AN is its thermal decomposition, either that of AN by itself or AN in mixtures with combustible binders in various solid propellants and gas generants.

One of the first reactions in the thermal decomposition of AN may be a proton transfer, a reaction that reverses its formation from ammonia and nitric acid. This reaction can be studied either experimentally by analyzing intermediates of the decomposition reaction or it can be modeled using modern methods of computational chemistry.

Aqueous solutions of AN are acidic and quite corrosive. Similarly, moist AN in metallized composite propellant formulations may react with the metal during storage [329]. Metallized AN propellants must be kept perfectly dry to prevent such reactions.

2.4.3.1 Reactions of Ammonium Nitrate with Organic Compounds

Reactions of AN with organic compounds most often lead to ignition and total destruction of the organics by combustion. This reaction is the reason for the popularity of AN as an oxidizer in solid propellants, gas generants, and explosives. Ammonium nitrate was combined with nitrate esters as early as the 1870s when Nobel incorporated AN in dynamites. In World Wars I and II, both sides added AN to their conventional organic explosives when supplies ran low. Usually this involved mixtures of AN with TNT (“amatols”), but this decreased the explosive potential. At the beginning of the insensitive munitions/low-vulnerability ammunition effort in the 1990s, in an effort to formulate more insensitive explosives, the military began adding AN to traditional organic explosives. At the same time, the commercial producers of AN blasting agents began to add surplus military explosives to their formulations to improve performance.

The first step in most reactions of AN with organic compounds is dissociation of AN into ammonia and nitric acid. Kinetic regularities of the heat release during the interaction of some organic compounds with AN were measured using DSC [330]. Despite the fact that many AN-based explosive or propellant formulations contain

a combination of two or more energetic species, mechanistic thermal stability studies of such combinations were lacking.

Pyroxylin is a partially nitrated cellulose used in lacquers and coatings. Collodion is a solution of pyroxylin in ether or ethyl acetate. The kinetics of heat release during the thermal decomposition of a mixture of AN and pyroxylin were studied to elucidate the mechanism of this process [331]. The temperature dependence of the constants in the kinetic equations gave the activation energies. The influence exerted by addition of diphenylamine on the rate of heat release in AN/pyroxylin mixtures was analyzed.

The kinetics, mechanisms, and rates of thermolysis of mixtures of AN with polynitro compounds depend on the type of nitro compound involved. Examples tested included bis(2,2,2-trinitroethyl) succinate, tetrakis(2,2,2-trinitroethyl) orthocarbonate, and technical-grade trinitrotoluene [332]. Mixtures of AN and TNT are widely used as castable explosives (amatols).

When the thermal stability of mixtures of AN with a variety of organic explosives was examined over the temperature range 443–593 K (170–320 °C), it was found that nitrate esters pentaerythritol tetranitrate (PETN) and nitrocellulose, the nitramines RDX and HMX, and the nitroarenes TNT and trinitroaniline destabilized AN [333, 334]. Ammonium nitrate, or its decomposition products, destabilized the organic explosives to varying degrees. All the organic explosives examined destabilized AN. The extent of destabilization was roughly in line with their own thermal stability. For RDX and PETN, the destabilization was only slight. Surprisingly, over the temperature range examined (489–553 K [216–280 °C]), AN and TNT had similar thermal stabilities, although at the lower temperatures TNT appeared to decompose slightly more slowly than AN. Based on DSC thermograms of AN, TNT, and their 1:1 mixture, when AN and TNT were mixed in a one-to-one ratio, the stability of both was adversely affected. In fact, with the exception of TATB, the presence of any of the monomolecular explosives, TNT, trinitroaniline (TNA), RDX, and PETN, increased the rate of AN decomposition. When AN was mixed one-to-one with either TNA, RDX, or PETN, there was a single exothermic DSC maximum at a temperature lower than that of neat AN. The mixture of AN with TNT exhibited two exothermic maxima. The first, with an exothermic maximum at a lower temperature than that of neat AN, was assumed to represent the AN decomposition, while the higher temperature exotherm was assumed to result primarily from TNT decomposition. When mixed one-to-one with AN, all three nitroarenes, TNT, TNA, and TATB, showed significant destabilization. PETN, a nitrate ester, most dramatically destabilized AN; the rate constant of AN mixture with PETN at 489 K (216 °C) was over 300 times faster than that of neat AN. RDX, a nitramine, was second in its ability to destabilize AN; the 489 K (216 °C) rate constant of AN decomposition was 30 times faster in the AN/RDX mixture than in a neat AN melt. Trinitroaniline and trinitrotoluene accelerated the decomposition of AN by roughly a factor of three, while TATB had little effect. Over the temperature range examined (473–553 K [200–280 °C]), AN was found to be less thermally stable in admixture with nitroarenes. The decomposition of all nitroarenes

was catalyzed by nitric acid, and the decomposition of TNT was found to be catalyzed by ammonia.

PSAN was prepared by incorporating copper(II) diammino dinitrate in the AN crystal lattice. A study of the effect of RDX on the thermal decomposition of PSAN showed that decomposition temperatures of PSAN and RDX were almost in the same temperature range [335]. The synergetic effect of the interaction between PSAN and RDX resulted in a net exothermic reaction of PSAN. The kinetic and thermodynamic parameters of the exothermic decomposition of a 1:1 mixture of AN and RDX were then computed from the DSC data. For heating rates from 2 to 15°C/min, the peak temperatures ranged from 222 to 248 °C. The activation energy was ~158 kJ/mol, and the pre-exponential factor was 1.23×10^{14} to $1.42 \times 10^{14} \text{ s}^{-1}$.

Ammonium nitrate crystals have a high affinity for trimethylamine and other alkylamine vapors in the air and may absorb amine vapors during storage, becoming more sensitive in the process [336].

2.4.4 Theoretical and Computational Studies of Ammonium Nitrate Decomposition Reactions

Quantum chemistry studies of proton transfer in gas-phase AN decomposition predict that a stable molecular form is the hydrogen-bonded $\text{H}_3\text{N} \cdots \text{HONO}_2$ neutral pair [337]. The most energetically favorable gas-phase reaction of nitric acid and ammonia in the absence of a solvent results in proton exchange, not proton transfer from acid to base.

Proton transfer reactions in vapor-phase ammonia–nitric acid clusters containing up to four component units were modeled, and the energy levels were calculated [338]. In a single AN unit, proton transfer between the nitric acid and ammonia unit does not occur, but the two molecules are strongly hydrogen-bonded. In a dimer cluster of two adjacent AN formula units $[\text{NH}_3\text{HNO}_3]_2$, proton transfer does occur, and the components are stabilized by ionic interactions. Ammonium nitrate solvated with a single ammonia $[\text{NH}_3\text{HNO}_3] \cdot \text{NH}_3$ or nitric acid $[\text{NH}_3\text{HNO}_3] \cdot \text{HNO}_3$ was also studied. The structure of clusters differed from that of free molecules. Using population analysis, the total electrostatic interaction between the components of each cluster was calculated. The binding energy of the neutral pair form was 46 kJ/mol (11 kcal/mol) greater than the $[\text{NH}_4^+] \cdots [\text{NO}_3^-]$ ion pair. It was argued that the magnitude of the total electrostatic interactions within the cluster determines whether proton transfer and ion formation will take place. Binding energies alone do not give a reliable indication of the likelihood of the occurrence of proton transfer. See also [339].

The decomposition mechanism of AN in the gas phase was characterized by means of complete basis set method calculations [340]. Five reaction channels were identified, leading to the formation of products (N_2 , H_2O , O_2 , OH , HNO , NO_3^-) found by experimental chemical analysis. The mechanism well explained the chemical hazard of AN, which is related to the exothermicity of the lowest decomposition channels. Furthermore, the high barrier to overcome in the rate-determining step

well explained the fact that the reaction is not usually spontaneous and requires a significant external stimulus for its onset. An accurate density functional theory benchmark study was then conducted to determine the most suitable exchange-correlation functional to accurately describe the reaction profile both in terms of structures and thermochemistry.

2.4.5 Analytical Methods for Ammonium Nitrate

Quality control of AN is extremely important because there are many commercial grades of AN available on the market, but few are suitable for use in propellants.

For an assay of AN, ammonium can be determined by quantitative distillation of ammonia in a Kjeldahl apparatus. Nitrate can be determined by quantitative reduction with ferrous ammonium sulfate. An alternative volumetric procedure was also investigated for assay based on the reduction of nitrate by titanous ion. However, this reduction was shown to be non-stoichiometric [341]. See also [342].

2.4.5.1 Military Specifications for Ammonium Nitrate

It appears that the military relies on commercial sources if it needs ANFO for bulk blasting jobs, such as in simulations of nuclear blasts using non-nuclear explosives. The quality control of AN procured for the U.S. government is assured by a series of military specifications (Table 23). Surprisingly, this specification also limits the amount of allowable boric acid (0.14 ± 0.03 mass-%). It is not known where the boric acid comes from and why it is detrimental to the intended use of AN.

Table 23: Military specifications for ammonium nitrate.

Designation	Title	Date	Pages
JAN-A-175	Ammonium Nitrate	30 May 1945	12
MIL-A-50460A (MU)	Ammonium Nitrate, Prilled (For Use in Ammunition)	15 Sep 1973	24

2.4.5.2 Moisture Content of Ammonium Nitrate

The maximum moisture content of AN intended for use in explosives allowed in military specifications is 0.15 mass-%. The recommended method for the analysis of moisture in AN is the American Society for Testing and Materials method E203-64, which

uses the Karl Fischer reagent containing pyridine, sulfur dioxide, methanol, and iodine.

A procedure for determining the water content of NiO PSAN using the Karl Fisher direct titration technique has been optimized [343]. The parameters investigated included possible side reactions, dissolution time, pH, and temperature. However, although accurate, straightforward, and simple, the method routinely used for AP was yielding non-reproducible results for PSAN, despite the fact that it is reportedly used for AN. A dependable procedure had to be developed to assess the moisture content of AN with the necessary degree of confidence. Recording the amount of water titrated against time revealed fading end points (i.e., extended time required to complete titration). Long titration times could have three causes: side reactions that produce water or consume iodine, a working pH outside the optimum range, or slow water release by PSAN while the titration is in progress. Other factors possibly affecting water determination results were the presence of nickel oxide, the mode of dissolution of the sample, the pH, and the temperature of the solution. See also [344].

2.4.5.3 Detection of Hidden Ammonium Nitrate

Detection of AN in improvised explosive devices (IEDs) is a major security issue for military and civil defense agencies. The vapor pressure of AN at room temperature is very low, and the vapors are difficult to detect with portable instrumentation.

A search for a system for the detection of AN in vehicles by remote nuclear quadrupole resonance (NQR) that depends on the penetration of radiofrequency (RF) magnetic fields inside certain metal enclosures, including full-scale vehicles, led to the design of a high-Q resonant probe [345]. The probe was shaped not only for optimal penetration of RF magnetic fields into vehicles but also for optimal rejection of RF interference and ease of shielding. A full-scale technical demonstrator was designed and built, and it successfully demonstrated the ability to generate and detect NQR signals from AN concealed within the trunk (boot) of a car and in the loading bay of a (metal-sided) van.

To detect and characterize the low-volatility components emanating from AN in IEDs, a sample of AN was sealed inside a stainless steel chamber while a laminar flow of air swept the headspace vapor components into a water impinger or cold trap for pre-concentration and subsequent analysis by ion chromatography [346]. Both collection methods were found to be 100% efficient for collecting nitric acid vapor, whereas the collection efficiency for ammonia was dependent upon the collection method and, for the water-impinging method, additionally upon the vapor concentration, humidity, and flow rate. Cold-trapping efficiency for ammonia was only 4% across all parameters studied. Water impinging was more efficient (20–70% recovery), but the efficiency varied according to each of the aforementioned variables. The characteristics of an AN vapor generated from a solid sample were found to vary as the sample approached equilibrium inside the chamber. Initially, large quantities of ammo-

nia were observed, but as a steady state was achieved within the laminar flow and a dynamic equilibrium established, the ratio of ammonia to nitric acid in the effluent vapor dropped, although never becoming equimolar. The ratio was strongly dependent upon humidity.

Known concentrations of AN were uniformly deposited onto commercially available surface-enhanced Raman scattering (SERS) substrates using a drop-on-demand inkjet printing system, and the phase changes observed after the deposition of AN under several solvent conditions were investigated [347]. Characteristics of the collected SERS spectra of AN demonstrated that knowledge of the exact nature of the AN samples deposited will result in improved ability to accurately and reliably “train” hazard-detection systems.

2.4.6 Thermal Stability and Decomposition of Ammonium Nitrate

The decomposition of AN does not follow a single reaction with a reproducible set of reaction products, but rather it follows a group of competitive reactions, the relative contribution of each depending on the rate of venting reaction products and operating under isothermal or adiabatic conditions. Table 24 is a list of possible decompositions with their energy output/input. The combustion reaction of AN with polyethylene is shown for comparison. The combustion reaction, of course, is much more energetic than the monopropellant decomposition.

Table 24: Decomposition reactions of ammonium nitrate.

Number	Reaction	ΔH , MJ/kg
1	$\text{NH}_4\text{NO}_3 \rightarrow \text{N}_2\text{O} + 2\text{H}_2\text{O}$	-0.73
2	$\text{NH}_4\text{NO}_3 \rightleftharpoons \text{NH}_3 + \text{HNO}_3$	+2.00
3	$2\text{NH}_4\text{NO}_3 \rightarrow \text{N}_2 + 2\text{NO} + 4\text{H}_2\text{O}$	-0.35
4	$4\text{NH}_4\text{NO}_3 \rightarrow 3\text{N}_2 + 2\text{NO}_2 + 8\text{H}_2\text{O}$	-1.16
5	$5\text{NH}_4\text{NO}_3 \rightarrow 4\text{N}_2 + 2\text{HNO}_3 + 9\text{H}_2\text{O}$	-1.54
6	$2\text{NH}_4\text{NO}_3 \rightarrow 2\text{N}_2 + \text{O}_2 + 4\text{H}_2\text{O}$	-1.47
7	$\text{NH}_4\text{NO}_3 + \text{CH}_2 \rightarrow \text{N}_2 + \text{H}_2\text{O} + \text{CO}_2$	-3.80

Data source: [61]

The effect of sample mass on the kinetics of the non-isothermal mass-loss process of molten AN was investigated using TGA-DTG [348]. The apparent Arrhenius parameters were shown to decrease with increasing sample mass. Using the conventional method of kinetic calculation, it was shown that the sample-mass-dependent variation in the apparent pre-exponential factor resulted from the use of fractional reaction in the kinetic expression. The value of the apparent activation energy varied

consequently to compensate the sample-mass-dependent change in the apparent pre-exponential factor on the regime of the mutual dependence of the Arrhenius parameters. This is known as the kinetic compensation effect. The more-specific Arrhenius parameters that are independent of sample mass were obtained by using the specific pre-exponential factor that is independent of sample mass, instead of the apparent pre-exponential factor.

A method to produce phase-modified AN (PMAN) by means of habit modification was investigated using potassium ferrocyanide [349]. The thermal stability and moisture absorption characteristics of PMAN were evaluated, and the energy of activation of decomposition reaction of AN, PMAN, and an admixture of AN-potassium ferrocyanide trihydrate were computed with non-linear integral isoconversional methods and used to measure their thermal stability. The moisture absorption characteristics were determined at 53 and 62% relative humidity, and the cyclic DSC analysis, a combination of non-isothermal and isothermal, was used to trace the phase behavior of the PMAN, indicating that PMAN and AN have comparable properties, suggesting similar processing and handling conditions.

The thermal and phase-change behaviors of PSAN films in a polymer matrix were characterized using neutron reflectometry and ellipsometry [350]. These techniques are highly sensitive to small changes in composition and density that occur during phase transitions. PSAN films were generally stable up to 433 K (160 °C), although small material loss may occur between 333 and 373 K (60 and 100 °C), which was attributed to solvent interactions with the PSAN. Crystallization of AN from super-saturated polymer is most common at thicker regions of the film, suggesting a critical nucleation thickness for the AN that can be avoided by making very thin films.

2.4.6.1 Slow Controlled Decomposition of Solid Ammonium Nitrate

The initial step of AN decomposition is melting. The next process is a reversible sublimation due to the measurable vapor pressure of AN, but without noticeable decomposition (Section 2.3.4). The species in the vapor phase are free ammonia and nitric acid. Chemical decomposition of AN leads to a mixture of nitrous oxide and water:

In addition to study of the slow thermal decomposition of AN using TGA, DTA, and DSC, a combination of these methods with simultaneous XRD offers insight into the phase changes and crystal transformations taking place in the AN crystals immediately prior to decomposition.

The rate of decomposition of AN was determined by the increased pressure when heated in a vacuum (10 mm Hg) at 443–473 K (170–200 °C) [351, 352]. Plots of mass loss/pressure increase vs. time indicated that AN decomposes autocatalytic at all temperatures. At 443 K (170 °C) the decrease in mass started after 3.5 h, whereas at 453, 463, and 473 K (180, 190, and 200 °C), it occurred after 2 h, 50 min, and 20 min, respectively.

As the temperature increased, the heterolytic decomposition increased and the share of homolytic decomposition decreased, resulting in a stoppage of the autocatalytic process. The autocatalytic process was probably due to HNO_3 , NO_2 , and H_2O formed during decomposition and remaining in the condensed phase. NO_2 was detected only in the gaseous products of decomposition at or above 458 K (185 °C).

The rate of decomposition of molten AN in a closed system at different mass/volume ratios ($[1-80] \times 10^{-3} \text{ g/cm}^3$) and at temperatures of 453–533 K (180–260 °C) was determined by measuring the changes in specific volume and vapor pressure with time [353]. At lower temperatures and greater mass/volume ratio, the reaction was self-accelerating, whereas at higher temperatures and smaller mass/volume ratios it was either first order or decelerating, with irregular behavior in between. The results were explained by postulating that dissolved reaction products, probably HNO_3 and H_2O , the solubility of which decrease with increasing temperature or decreasing mass/volume ratios, may accelerate the decomposition.

Most AN decomposition studies have used IR or MS to analyze the gaseous decomposition products, but some of the products are IR-inactive and cannot be detected by IR. A complete gas analysis is possible by repetitive and time-resolved gas chromatography [354]. The thermal decomposition of AN and associated mixtures in the range 443–473 K (170–200 °C) was studied by measuring the rate of evolution of nitrous oxide using a flow system in conjunction with gas chromatography, enabling measurements to be made at temperatures of practical importance not covered in previous investigations. The rate constant calculated from the data for pure AN was compared with the values obtained by other researchers. The effects of several metal ions, water, or monoammonium phosphate on the decomposition rate were studied by this method, but no clear pattern emerged from the results.

During DSC examination of the same AN samples, the salt undergoes the transformations $\text{IV} \rightarrow \text{III}$ and $\text{IV} \rightarrow \text{II}$ in parallel, then undergoes the crystal transformations $\text{III} \rightarrow \text{II} \rightarrow \text{I}$, and finally melts [355]. The investigation conditions and the transformation history of the samples do not influence the crystal transformations during thermal analysis very much.

Simultaneous thermal and gravimetric analysis (DSC-TGA) with heating rates from 2.5 to 20 K/min was used for the thermal characterization of PSAN containing 1.0% of NiO and 0.5% of Petro (an anti-caking agent) as additives [356]. The main features of the thermal behavior of PSAN, i.e., two phase transitions, melting, and decomposition, were quite reproducible. Non-isothermal kinetic analysis was then used to estimate the Arrhenius parameters of the decomposition process by applying both a single-curve method and two isoconversional methods to the TGA data. Under the conditions of this study, the activation energy was $81.4 \pm 3.5 \text{ kJ/mol}$ and the pre-exponential factor was $(5.63 \pm 0.01) \times 10^5 \text{ s}^{-1}$. These data accurately described the process over a wide range of the kinetic analysis.

Major accidents involving overheating of large quantities of packaged AN or ANFO have occurred. To study these events on a smaller scale, convenient laboratory quantities to investigate thermal decomposition properties are generally less than 1 kg. In order to provide information applicable to real-life situations, any laboratory study must use techniques that minimize heat losses from the samples to their environment. Two laboratory-scale calorimeters providing an adiabatic environment were used to study the slow decomposition of AN: an accelerating rate calorimeter and an adiabatic Dewar calorimeter [357]. Experiments were performed on pure and packaged AN and ANFO. The effects of sample mass, atmosphere, and formulation on the resulting onset temperatures were measured. The results from the two techniques were compared, and a method to extrapolate these results to large-scale inventories was proposed.

See also [296, 358, 359]. Figure 24 shows a baseline DSC thermogram of dry, pure AN. This thermogram was the baseline for a study on the effect of ADN on AN stabilization [277].

Pressure TGA-DTA was used to study the thermal decomposition of AN under open and non-isothermal conditions as functions of the sample size, heating rate, flow rate of purge gas, shape of sample pans, and pressure [360]. The thermal decomposition was simulated using a physicochemical model. The thermal decomposition of AN consisted of a chemical reaction and a thermal dissociation process. The model considered thermal dissociation as a first-order diffusion model and succeeded in reproducing the experimental results.

The thermal properties of AN were studied using pressure differential scanning calorimetry (PDSC), and evolved gases were analyzed by combining PDSC with FTIR and mass spectrometry [361]. PDSC results showed that AN undergoes an exothermic reaction above 0.3 MPa, and this exothermic reaction offsets the endothermic reaction of AN as the ambient pressure is increased. Evolved-gas analyses demonstrated that AN decomposition generates N_2O and H_2O during the exotherm and generates NO_2 throughout the endotherm. The heat flow associated with the thermal decomposition of AN was simulated, assuming that the decomposition rate of AN is given by

$$-dC_{AN}/dt = 10^{9.4} \exp(-126000/RT) C_{NH_4^+} \times C_{HNO_3},$$

that the heat of reaction is 105 kJ as per the reaction equation

and that $C_{NH_4^+}$ and C_{HNO_3} are constant due to chemical equilibrium. The heat-flow curves calculated in this manner were in good agreement with experimental DSC curves obtained at 1.1 MPa.

2.4.6.2 Effect of Moisture on Slow Controlled Decomposition of Solid Ammonium Nitrate

^{15}N - and ^{18}O -isotope substitution has been used to resolve questions about the origin of the N-atoms in the formation of N_2O by decomposition of AN [206]. As part of this investigation about the possible participation of H_2O in the decomposition reactions of AN, a sample of AN was very carefully dried to remove all traces of moisture by heating it to 423 K (150 °C) and evacuating it overnight in hard vacuum from a mercury diffusion pump. All AN had sublimed to the cool section of the tube above the furnace. The sample bulb was disconnected from the pump and connected to a pressure gauge. The furnace was raised to surround the AN, and the temperature was raised slowly to 573 K (300 °C). The result was very surprising: There was no decomposition detectable manometrically for more than an hour. The experiment was interrupted, and the sample was allowed to cool off. A small amount of water vapor was admitted to the system, and heating was resumed. This time the decomposition started at 453 K (180 °C). This experiment was reproducible using a fresh sample of AN.

In a parallel experiment, the admission of dry N_2O to the bone-dry AN had no effect, and it neither aided nor retarded the decomposition of AN. In order to answer the question of whether H_2O participates in the AN decomposition reaction, the bone-dry AN was moistened with H_2O containing 1.5% H_2^{18}O and decomposed above 453 K (180 °C). The $^{18}\text{O}/^{16}\text{O}$ ratio of the N_2O thus formed was the same as that with normal water (within 0.3% error limit), indicating that water does not participate in AN decomposition.

It was attempted to determine the influence of a great number of successive rhombic $\rightarrow$ monoclinic, monoclinic $\rightarrow$ trigonal, and trigonal $\rightarrow$ cubic crystal transformations on the AN crystal transformation energies [362]. The energies of prilled AN crystal transformations from rhombic into monoclinic, from monoclinic into trigonal and from trigonal into cubic were observed as functions of the number of previous crystal transformations (5, 10, 15, 20, 35, 50 rhombic $\rightarrow$ monoclinic transitions) and the moisture content (0.01–1.21 mass-% H_2O).

During the production of AN, the process water is evaporated, leaving supersaturated and superheated solutions behind. Under these conditions, just prior to allowing the hot product to crystallize, there may be incipient decomposition of AN that would contaminate the product and may be a process hazard. The decomposition of aqueous AN at elevated temperatures and pressures was examined as a function of chloride, nitrate, and total acidity [363]. Catalysis requiring both chloride and acid was observed in solutions containing 20 mass-% AN at 453 K (180 °C). Nitrous oxide and dinitrogen were generated in a 4:1 ratio below 0.2M $[\text{H}^+]$. Dinitrogen formation correlated with the production of additional acidity by the reaction

The second-order dependence of the decomposition reaction on $[\text{H}^+]$ is consistent with the reversible formation of NO_2^+ . Incorporation of ^{18}O into the N_2O product, as well as

the inverse deuterium isotope effect, supported this conclusion. A novel mechanism based on the intermediacy of NO_2Cl was proposed for the chloride catalysis and contrasted with the radical-based pathways operational in molten AN decompositions. Isotope-labeling experiments using $^{15}\text{NH}_4\text{NO}_3$ led to the formation of ^{15}NNO -labeled nitrous oxide and the dinitrogen products $^{15}\text{N}^{15}\text{N}$ and $^{14}\text{N}^{15}\text{N}$ in a 1 : 3 ratio. Decomposition of $\text{NH}_4^{15}\text{NO}_3$ produced only $^{14}\text{N}^{15}\text{NO}$ and $^{14}\text{N}^{15}\text{N}$. This agreed with the following reaction sequences:

These results bear on the industrial production of AN and suggest conditions under which industrial nitrous oxide emissions might have an impact on the global N_2O budget.

2.4.6.3 Effect of Ammonia on Slow Controlled Decomposition of Solid Ammonium Nitrate

Similar to the detailed studies on the effect of ammonia in retarding the decomposition of AP (Volume 1, *Encyclopedia of Oxidizers*, chapter “Perchlorate Oxidizers”), detailed experiments have shown that the decomposition of AN is likewise retarded in the presence of excess ammonia. A study of the effect of the partial pressure of gaseous ammonia on DTA and TGA thermograms of AN showed variations of the thermal effect and decomposition rate [364]. These data constitute a basis for analysis of the factors that determine the decomposition and equilibrium of exothermic and endothermic processes.

2.4.6.4 Effect of Acidity on Slow Controlled Decomposition of Solid Ammonium Nitrate

In order to study the effect of acid catalysis on the thermal decomposition of AN, weighed samples of AN were placed into carefully dried Pyrex tubes that were then evacuated and sealed [365, 366]. The sealed tubes were immersed for varying lengths of time in a thermostatted oil bath at 488 or 503 K. At the end of the test period, the tubes were quickly cooled to room temperature, frozen in LN_2 , and broken under water, and their contents were rinsed into a beaker for titration of free acid and ammonium ion before and after the addition of formaldehyde. Other AN samples were doped with a known amount of HNO_3 before the vials were sealed. The molar ratio of AN : HNO_3 was varied between 625 and 6900. The acid addition caused accelerated AN decomposition. On the other hand, tests with varying ullage volumes showed that

ammonia retards the AN decomposition. A mechanism involving the intermediate formation of nitramide was proposed for the AN decomposition:

The surface-to-volume ratio also affected the rate of AN decomposition. If additional surface was added in the form of glass wool, the rate of AN decomposition was reduced because the decomposition of HNO_3 was heterogeneously catalyzed by the added surface, and formation of NO_2 was observed.

The decomposition of molten AN was investigated manometrically at 473 K (200 °C) [367]. HNO_3 accumulated as the reaction proceeded, and its concentration increased with temperature and with the degree of filling of the reaction vessel. The decomposition rate increased in the presence of added HNO_3 , particularly when it was highly concentrated. Small amounts of H_2O also accelerated the initial decomposition, but large amounts of H_2O inhibited the rate of decomposition.

Because the first AN dissociation product to decompose is nitric acid, the effect of nitric oxide and nitrogen dioxide on AN decomposition had to be investigated by adding NO and/or NO_2 to the decomposition chamber [368]. The effect of the partial pressures of NO and/or NO_2 in the gas phase at 0–0.1 MPa on the profile of DTA and TGA curves for AN, on its rate of decomposition (from 388 to 548 K), and on nitric acid concentration in the condensed phase have been investigated. Both compounds were found to increase the isothermal decomposition rate and to lower the temperature of initiation. The results of these studies have led to the conclusion that as the factors causing an increase in the concentration of both compounds in ammonium nitrate increase, the possibility of autoignition or explosion also increases.

In the presence of traces of concentrated sulfuric acid, the self-accelerating decomposition temperature (SADT) of AN is lowered substantially [369]. This is important when assessing the stability of AN/ammonium sulfate mixtures often used as fertilizers. The explosion in Oppau, Germany, involved such a mixture.

The heat release during decomposition of pure AN and its mixtures with inorganic acids was analyzed in a heat flux calorimeter model C80 [370]. The results showed that mixtures of AN with acids are more unstable than pure AN. The AN decomposition reaction is catalyzed by acids. The calculated SADTs of AN mixtures with acid are much lower than those of pure AN. In continuation of this work, the influence of HCl on AN decomposition was studied using the same C80 calorimeter [371]. The data were analyzed to show the different decomposition reactions of AN and its mixtures with HCl. The SADTs of AN and its mixtures with HCl in 25-kg standard packages based on the thermal explosion theory were calculated and compared. The results showed that AN decomposition can be catalyzed by HCl and that the activation energy of AN with HCl is smaller than that of pure AN. See also [372].

2.4.6.5 Effect of Additives on Thermal Decomposition of Ammonium Nitrate

The kinetics of the thermal decomposition reaction of analytically pure AN, commercially pure AN, and mixtures of analytically pure AN and NaNO_3 have been investigated by means of non-isothermal DSC and TGA at various heating rates of 2, 4, 6, and 8 K/min [373]. The results showed that the decomposition reaction rate in the conversion degree range of $0.0 < \alpha < 0.4$ for AN is controlled by nucleation and growth, and the mechanism function is an Avrami-Erofeev equation with $n = 2/3$. The decomposition process of the mixture in the conversion degree range of $0.0 < \alpha < 0.4$ is classified as a one-dimensional phase-boundary reaction and the mechanism function is the contracting sphere (volume) equation with $n = 1/3$. The kinetic equations of analytically pure AN and the mixture are

$$\frac{d\alpha}{dT} = 109.43(1 - \alpha)[- \ln(1 - \alpha)]^{\frac{1}{3}} \exp\left(-1.319 \times \frac{10^4}{T}\right)$$

and

$$\frac{d\alpha}{df} = 109.4(1 - \alpha)^{\frac{2}{3}} \exp\left(-1.566 \times \frac{10^4}{T}\right)$$

respectively, indicating that NaNO_3 addition can improve the thermal stability of AN.

A DSC study of the effect of RDX or HMX on the thermal decomposition of PSAN showed that the decomposition temperatures of PSAN and RDX are almost in the same temperature range [374, 375]. The decomposition of PSAN was endothermic and that of RDX was exothermic, while that of a 1:1 mixture of the two was exothermic with a net heat release in excess of that of the individual reactions, which was attributed to a combustion reaction among the decomposition products of PSAN and RDX. Though HMX decomposed at a higher temperature, in presence of molten PSAN a substantial portion of it decomposed at a lower temperature along with PSAN with a net excess heat release, again due to a combustion reaction.

Mixtures of AN and guanidinium nitrate have improved thermal stability [376]. The kinetics of heat release in thermal decomposition of guanidinium and ammonium nitrates and their mixtures in the liquid phase in a calorimeter were investigated. The temperatures and ΔH values of melting of the initial salts and their eutectic mixture were determined.

Runaway reactions present a serious threat to the chemical process industry and surrounding communities. Such reactions occur time and time again, often with devastating consequences. The root causes associated with AN explosions during storage and the effects of different types of fertilizer additives on AN thermal decomposition need to be studied. A reactive systems screening tool (RSST) has been used for reactivity evaluation and to better understand the mechanisms that result in explosion hazards [377]. The results are reported as onset of exotherm temperature, rate of temperature and pressure rise, and maximum temperature. The runaway behavior of AN

has been studied as a solid and as a solution in water. The effects of additives such as sodium sulfate (Na_2SO_4) and potassium chloride (KCl) have also been studied. The results showed that the presence of Na_2SO_4 can increase the onset temperature of AN decomposition, thus acting as an AN thermal decomposition inhibitor, while KCl tends to decrease the onset temperature, thus acting as an AN thermal decomposition sensitizer.

Potassium chloride is not a likely contaminant of AN, and contact of AN with KCl would be possible in potassium (sylvite) mines where ANFO is used as a blasting agent. KCl might also be part of fertilizer mixtures. The thermal decomposition of AN and KCl mixtures was investigated using DSC, and the evolved gas was analyzed using TGA with MS and pressurized DSC coupled with MS (TG-DTA-MS and PDSC-MS) [378]. DSC measurements of AN/KCl mixtures in sealed and sealed-separated sample pans showed a sharp exothermic decomposition and lower onset temperature than pure AN, whereas AN/KCl in an open pan exhibited an endothermic reaction. In the sealed-separated pan, a separator with a pinhole divided the KCl and AN physically, and only the evolved gas could interact with both AN and KCl. TG-DTA-MS results showed that HCl gas was evolved from AN/KCl, which indicated that the reaction of KCl with HNO_3 dissociated from AN formed HCl, with subsequent destabilization of AN. However, the TG-DTA-MS results did not indicate the violent exothermic reaction due to using an open pan and ordinary pressure conditions. PDSC-MS was used to observe a sequence of two exothermic reactions of AN/KCl and to analyze the evolved gases from the reactions. A violent first exothermic reaction was accompanied by a large amount of N_2 and N_2O evolution without H_2O , and a second exothermic reaction was accompanied by evolution of H_2O , N_2O , and other gases. It was concluded that AN reacts with KCl to produce Cl radicals via HCl and NO_2Cl , and the Cl radical triggers a radical chain reaction of AN.

Spray-dried AN particles were prepared from AN, potassium nitrate as a phase stabilizer, and a polymer (e.g., polyvinyl alcohol, carboxymethylcellulose salt, and styrene-butadiene latex) for moisture proofing [267]. The crystal transformation behavior of AN/ KNO_3 /polymer particles was investigated using DSC and TGA. The results confirmed that AN can be phase-stabilized by the addition of KNO_3 . Carboxymethylcellulose ammonium salt and polyvinyl alcohol, which were both added as polymer components for moisture proofing, also acted as phase stabilizers to retard AN crystal transformations. The thermal stability of the AN/ KNO_3 /polymer crystals was enhanced by the thermal properties of the polymer components [268].

Ammonium nitrate has been modified with non-explosive additives to prevent its use in illegitimate, clandestine bomb making. The thermal stability of normal AN and anti-explosive additive-treated AN (AEAN) was examined using ARC, and apparent activation energy and pre-exponential factor were calculated [379, 380].

2.4.6.6 Effects of Particle Size and Porosity on Decomposition of Ammonium Nitrate

For many propellant formulations, similar to what is being done for AP, it would be desirable to use finely ground AN to increase the burning rate. The decomposition of AN may depend on the particle size.

According to DSC measurements, AN samples with particle sizes between 0.062 and 2 mm have different structural phase transition paths in the temperature range 298–373 K (25–100 °C) [381]. Samples with particle sizes of about 2 mm underwent the transition path IV → III → II, whereas those with particle size near 0.06 mm were more likely to undergo the transition path IV → II.

Ammonium sulfate and AN aerosols can be found in polluted atmospheres and contribute to energy balance and contaminant transport. For this reason, the effect of particle size on AN decomposition and phase changes has been examined by atmospheric chemistry investigators.

The bulk density of porous (“expanded”) AN is typically 0.35–0.6 g/cm³. The thermal stability of expanded AN was examined using TGA and DSC and was found to be the same as that of solid, non-porous AN [382].

2.4.6.7 Effects of Pressure on Slow Controlled Decomposition of Solid Ammonium Nitrate

If AN is decomposed at high pressure (either externally applied gas pressure or self-decomposition in a closed volume under the pressure of its decomposition products), the rate of decomposition and composition of its decomposition products can be quite different.

In order to study the decomposition of AN under pressure developed by its own decomposition products, samples of absolutely dry AN were sealed in glass capillary tubes and immersed in a molten metal bath for varying lengths of time. The capillaries were quenched, and the gas evolved was captured and analyzed [383, 384].

The kinetics of AN thermal decomposition were studied with DTA in the pressure range from atmospheric pressure to 1.0 GPa [385]. The decomposition under pressure was shown to obey a zero-order equation, with a constant proportional to the initial free HNO₃ concentration in the sample. The structural transitions in AN were found to affect its exothermic interaction with boron. The volume increase on melting of AN is 0.072 cm³/g.

If AN is heated at low pressures, it may sublime and dissociate before it decomposes. The thermal decomposition of AN in the gas phase has been studied at 423–456 K by pyrolysis/MS under low-pressure conditions using a reactor coated with boric acid [386, 387]. The sublimation of AN at 423 K was proposed to produce equal amounts of NH₃ and HNO₃, followed by the decomposition of HNO₃ according to

(where M = third-body and reactor surface). The absolute yields of N₂, N₂O, H₂O, and NH₃, which can be unambiguously measured and quantitatively calibrated under con-

stant pressure, were kinetically modeled using a detailed [H,N,O]-mechanism established earlier for the simulation of $\text{NH}_3 + \text{NO}_2$ reactions and ADN decomposition reactions. Since the homogeneous decomposition reaction of HNO_3 itself was found to be too slow to account for the consumption of reactants and the formation of products, the investigators also introduced the heterogeneous decomposition of HNO_3 in their kinetic modeling. The heterogeneous decomposition rate of HNO_3 was determined by varying its rate to match the modeled result to the measured concentrations of NH_3 and H_2O . The rate could be represented by

$$k_{2b} = 7.91 \times 10^7 \exp(-12600/T) \text{ s}^{-1},$$

which appeared to be consistent with those reported by others for HNO_3 decomposition in glass reactors at higher temperatures.

2.4.6.8 Effect of Contaminants on Decomposition of Ammonium Nitrate

A comparison of two grades of commercial AN showed that a product made in the United States contained ~1% of a hydrocarbon and 5% kaolin to confer free-running properties of the granules, but a product obtained from the United Kingdom was nearly pure AN and was considered safer under normal conditions of storage and transport [388].

The location of the maximum of the exotherm peak of AN decomposition in a DTA ($543 \text{ K} = 270^\circ\text{C}$) was not affected by addition of 5 mol-% NaF, NaI, NaBr, or $(\text{NH}_4)_2\text{SO}_4$, but the ΔT peak height increased somewhat [389]. The exotherm maxed out at a much lower temperature ($455 \text{ K} [182^\circ\text{C}]$) if 5 mol-% $(\text{NH}_4)_2\text{Cr}_2\text{O}_7$ was added to the AN. NaCl and NH_4Cl had in-between effects, but chlorides are the most likely contaminants in AN.

The decomposition of AN containing 1% NH_4Cl was examined by heating the samples at $473 \text{ K} (200^\circ\text{C})$, removing small samples periodically and dissolving them in water, and plotting the pH of 10% solutions vs. time [390]. The decomposition of AN is a complex autocatalytic reaction, consisting of (1) hydrolysis of nitrate, (2) thermal decomposition of resulting HNO_3 , and (3) reaction of chloride with NO_2 , giving NO_3^- , NO, and free chlorine. Free chlorine is an activator, as it oxidizes NH_3 , and some reactions can be explained by free radical formation of some of the intermediates.

Chloride and various transition metal ions, notably chromium and copper, exhibit an unexpectedly large synergistic effect in the catalysis of the thermal decomposition of AN [391]. In the case of copper(II) and chloride, a proposed mechanism involves the operation of redox cycles in which reactions occur by electron transfer in chloro-bridged activated states. NH_4^+ and NH_3 are oxidized to NH_3^+ and NH_2 , and NH_2Cl is produced by reaction of NH_2 . The original copper(II) catalysts are then regenerated through oxidation by NO_2^+ and NO^+ . The proposed mechanism for chromium catalysis depends on the participation of dichromate in a fused-salt acid-base reaction with nitrate in which nitronium and chromate ions are formed. Any metal capable of forming chloro complexes of reasonable stability in two oxidation states differing by one

electron unit makes a good catalyst. Chromium is a special case in which oxo complexes are believed to be involved. An attempt was made to correlate synergistic catalytic activity with chloride ion with various other properties of the metal ions, such as stability constants of complexes, ionization and oxidation potentials, and ionic and atomic radii. All chromium species added to the decomposing acidic AN melts immediately assumed the characteristic orange color of dichromate. This color persisted throughout the course of the reaction.

The activation energy and frequency factor of the thermal decomposition of AN/ammonium chloride mixtures were determined volumetrically by catching the gases formed during decomposition and ramping up the temperature with a linear temperature profile heating rate [392, 393]. Small amounts of chloride ions lowered the thermal stability of AN markedly.

The rate of disappearance of ammonium ion in chloride-catalyzed nitric acid mixtures at 373 K (100 °C) can be expressed by the rate equation

$$d[\text{NH}_4^+]/dt = -k[\text{H}^+]^n[\text{NO}_3^-]^o[\text{Cl}^-]^p[\text{NH}_4^+],$$

where $k = (2.430 \pm 0.186) \times 10^{-7} \text{ s}^{-1}$, $n = 2.426 \pm 0.034$, $o = 3.096 \pm 0.039$, and $p = 1.295 \pm 0.035$ [394]. Fluoride and bromide had no catalytic activity.

A study of the effect of adding 0.5–1 mass-% of ammonium molybdate $(\text{NH}_4)_2\text{MoO}_4$, boric acid H_3BO_3 , zinc sulfate ZnSO_4 , magnesium sulfate MgSO_4 , iron(II) sulfate FeSO_4 , copper(II) sulfate CuSO_4 , cobalt(II) sulfate CoSO_4 , or manganese(II) sulfate MnSO_4 on the thermal stability of AN at 493 and 513 K (200 and 220 °C) showed that FeSO_4 and CuSO_4 catalyzed AN decomposition and MgSO_4 retarded it [395].

An examination of the mechanism of AN thermal decomposition in the temperature regime of 573–673 K (300–400 °C) showed that the first step in fused NH_4NO_3 decomposition is dissociation into NH_3 and HNO_3 [396]. At temperatures below 573 K (300 °C), its further decomposition was said to be governed by the rate at which nitronium ion is formed from nitric acid. As a result, the decomposition rate is sensitive to exogenous water, ammonia, and nitric acid. Above 513 K (340 °C), the sensitivity of the decomposition to these additives was substantially less. It was proposed that a free-radical decomposition mechanism is dominant in this temperature regime and that the rate-controlling step is homolysis of nitric acid to form nitronium and hydroxyl radical, the rate being the same for the liquid and vapor-phase reaction.

Much of the work on the effect of contaminants on the thermal stability of AN and AN formulations was done for the use of AN in ANFO blasting agents, but the rocket propellant and gas generant applications will benefit from the results of this work, and this is why we reference it here. The effects of various anions on the thermal stability of AN/fuel oil and an AN emulsion were examined using DSC and conventional methods [397, 398]. It was found that salts of weak acids, due to their basicity, stabilized these formulations. The added stability was enough to counteract the influence of ferric or ferrous salts, frequent contaminants that normally enhance decomposi-

tion. Ammonium cation, the salt of a weak base, slightly destabilized the AN compositions. Sodium and calcium nitrates, where both anions and cations were salts of strong acids and strong bases, respectively, did not appear to affect thermal stability.

On 21 September 2001, about 300–400 tons of AN exploded at the Grande Paroisse (AZF) fertilizer plant in Toulouse, France. The explosion killed 31 people and injured over 200. An internal investigation by Grande Paroisse's parent company, Atofina, has focused on three possible causes:

- (1) scattering of metal fragments on the fertilizer storage facility by a plant explosion
- (2) anomalies in the paperwork
- (3) contamination of AN by other chemicals produced at the site

One of the other chemicals produced at the site was the sodium salt of dichloroisocyanurate (sodium 3,5-dichloro-2,4,6-trioxo-1,3,5-triazinan-1-ide, sodium troclosene, DCCNa), a chemical that is often used as a disinfectant for swimming pools and as a biocide, industrial deodorant, and detergent. In an effort to find a cause of the accident, DCCNa was added to AN at concentrations of 0.01, 0.03, 0.1, 0.5, and 1 mass-% [399]. A heat flux calorimeter and an accelerating rate calorimeter were used to analyze the thermal decomposition of AN and its contaminated mixtures. The results showed that the initial decomposition temperature of the mixture decreased markedly compared to that of pure AN. It was suspected that DCCNa catalyzes the decomposition of AN through key steps, including the synergism between HNO_3 and Cl_2 . However, the results of the BAM 50/60 steel tube detonability test did not show a distinct effect of added DCCNa on the detonation behavior of AN.

In a similar study, the thermal hazards of mixtures of AN and the sodium salt of dichloroisocyanuric acid were investigated using DSC, ARC, TGA, simultaneous TG-DTA-FTIR-MS, heat flow calorimetry (HFC), and isothermal nanocalorimetry [400]. The sensitivity of the mixtures to impact, friction, and electrostatic discharge (ESD) was also determined using standard sensitivity test methods. ARC experiments on a 2-g sample of AN/DCCNa mixtures in humid air revealed an onset temperature for exothermic thermal decomposition as low as 310 K (37 °C). Isothermal nanocalorimetry experiments revealed three overlapping exothermic peaks that resulted in a total energy release of 0.4 kJ/g over the course of 13 d at 298 K (25 °C). Simultaneous TG-DTA with FTIR and MS detectors identified the reaction products as CO_2 , HCl , N_2 , N_2O , NO_2 , and Cl_2 . The results from this study suggested that accidental mixing of bulk quantities of these materials would pose a considerable hazard and should be avoided.

Prilled commercial fertilizer-grade AN is often coated with limestone or dolomite powder as an anti-caking agent. Thermal decomposition of AN and its coated prills was studied using combined TGA-DTA-FTIR under dynamic heating conditions up to 1173 K (900 °C) at a heating rate of 10 °C/min [401]. The amount of additives used was 5, 10, or 20 mass-% or was based on the mol ratio of $\text{AN}/(\text{CaO}, \text{MgO}) = 2:1$ in the blends. The results of analyses of the gaseous compounds evolved during thermal treatment of neat AN indicated some differences in the decomposition of AN in air and in N_2 .

During the thermal treatment of AN blends with CaCO_3 , MgCO_3 , natural limestone, and dolomite samples, the decomposition of AN proceeded through a completely different mechanism depending on the origin and the content of additives, partially or completely, through the formation of $\text{Mg}(\text{NO}_3)_2$ and $\text{Ca}(\text{NO}_3)_2$.

Additional runs at 2, 5, and 20 °C/min in a stream of dry air were made for calculation of kinetic parameters [54]. The results of TGA-DTA-FTIR and the variation of the value of activation energy along the conversion parameter α indicated the complex character of the decomposition of neat AN as well as of the interactions occurring during thermal decomposition of AN prills coated with limestone or dolomite powder.

Moist AN is acidic, and AN stored in steel containers is likely to contain corrosion products in the form of iron(III) nitrate $\text{Fe}(\text{NO}_3)_3$. The influence of iron(III) nitrate on the thermal stability of AN was measured with ARC and constant temperature calorimetry [402, 403]. It was shown that iron(III) nitrate catalyzes AN decomposition; it will decrease the onset of decomposition exotherm temperature of AN by 60 °C. The catalytic effects of iron(III) nitrate on AN decomposition as measured by ARC or constant temperature thermal decomposition are the same. Based on ARC data, the activation energy and pre-exponential factor were $f(\alpha) = 1 - \alpha$, $E_a = 195.41 \text{ kJ/mol}$ and $A = 2.08 \times 10^{19} \text{ s}^{-1}$. The experiments showed that once the iron ions fuse into the AN, thermal stability will decrease remarkably. The kinetics of AN decomposition can be used to calculate the critical temperatures for AN decomposition with and without the presence of iron(III) nitrate, based on the Frank-Kamenetskii model of thermal runaway explosions.

As part of an ongoing investigation into a cause of the AN explosion in Toulouse, France, in September 2001 and in continuation of earlier compatibility studies of AN with the sodium salt of dichloroisocyanuric acid, a detailed theoretical study was performed to better understand the involved mechanisms, considering the reaction between AN and the sodium salt of dichloroisocyanuric acid (SDIC) [404, 405]. The gas-phase decomposition mechanism of the mixture was investigated and fully characterized by means of density functional theory calculations. Beyond the complete characterization, in terms of intermediate structures and energies of the decomposition pathways, the results pointed toward the role of water in catalyzing the decomposition reaction, through a significant decrease of the activation energy of the rate-determining step. These results, in qualitative agreement with calorimetric experiments, confirmed the instability of the AN + SDIC wet mixture and the incompatibility mechanism between these two chemicals.

In another study of the Toulouse explosion, several chloride salts, including ammonium chloride, barium chloride, calcium chloride, sodium chloride, and potassium chloride, were added to AN at concentrations of 0.05, 0.1, 0.5, 1, and 2%, respectively, and DSC and a heat flux calorimeter with high sensitivity were used to measure the decomposition of AN and its mixtures with these impurities [406]. All of the results demonstrated that the addition of a small amount of chloride caused a significant decrease in the initial decomposition onset temperature of AN by nearly 100 °C and an

increase of heat release from the reaction. The intensity of the decomposition of AN with and without added impurities was also examined by a modified pressure vessel test (MCPVT) in which the rate of pressure rise of AN in the presence of chlorides in the MCPVT was a multiple of that of pure AN. However, in the BAM 50/60 steel tube test, no detonation was observed for either pure AN or contaminated AN under the test conditions.

The effects of inhibitors, confinement, and heating rate on AN thermal decomposition were studied in the presence of different types of additives, including sodium bicarbonate, potassium carbonate, and ammonium sulfate at two concentrations, 2.8 and 12.5 mass-%, using an RSST [407]. The results showed that the three salts are good inhibitors for AN. The effect of confinement was tested by observing AN decomposition under five different initial pressures, varying from ambient pressure to 1.29 MPa gauge (187 psig). It was concluded that confinement aggravates explosive decomposition. The effect of heating rate was studied by heating AN under two heating rates of 0.25 and 2°C/min. The slower the heating rate, the lower the onset of exotherm temperature detected.

Properly selected calcium and magnesium carbonates (fertilizer additives) may increase the thermal stability of AN [408]. The influence of the carbonate mineral type and composition on phase transitions and the decomposition process of fertilizer-grade AN was measured using DTA and TGA coupled with MS. The results showed that too high a level of carbonate reactivity can cause problems during the production of fertilizer, reducing the effectiveness of the filler in a final product.

The kinetic parameters of AN/KCl thermal decomposition over a range of KCl mass fractions were experimentally measured using an advanced reactive chemical screening tool [409]. Based on experimental findings and past literature review, an AN/KCl decomposition mechanism was proposed, proceeding along four separate pathways: **(1)** a direct AN main decomposition pathway, **(2)** an indirect AN main decomposition pathway via chlorine radical, **(3)** a direct pure AN side decomposition pathway, and **(4)** an indirect AN side decomposition pathway via chlorine radical. KCl addition not only accelerated the AN decomposition but also increased the reaction heat release. See also [410–412].

2.4.6.9 Effect of Catalysts on Slow Controlled Decomposition of Ammonium Nitrate

There is hardly any decomposition in solid AN below the melting point. Most investigations of the effect of additives and stabilizers on the rate of AN decomposition have therefore worked with molten AN.

An excellent summary of the effect of catalysts on the decomposition of AN is a dissertation by Franco from 1968 [413]. Considering the early date of this work, it has an amazing amount of detail and a good discussion of the state of knowledge of AN decomposition kinetics at that time.

Ions of many transition metals, most of all chromium salts, catalyze the decomposition of AN in small quantities and at moderate temperatures below its melting point.

The catalytic activity and the overall rate of decomposition accelerates once the AN has melted. Metals investigated include Mn, Co, and Cu cations [414]. Chromium ions are a very good catalyst, particularly if they are soluble in molten AN [415, 416]. The effect of chromium compounds on the kinetics of decomposition of liquid AN has been studied in the temperature range 460–520 K [417]. Chromium compounds soluble in liquid AN were found to be very effective catalysts. For low concentrations of catalyst, the principal products of decomposition were N_2 , N_2O , H_2O , and HNO_3 . The catalyzed decomposition, like the uncatalyzed decomposition, is inhibited by NH_3 and H_2O and promoted by HNO_3 . Low concentrations of chromium catalyst can produce easily detected changes in the course and rate of decomposition, and higher concentrations can result in an explosive rate of reaction. The metals studied for lowering the thermal stability of AN are the same ones that are also good candidates for burning-rate enhancing additives for AN in solid propellants.

Metal Oxide Catalysts for AN Decomposition

Metal oxides of copper, nickel, and cobalt react with molten AN to form ammino complexes that catalyze the decomposition of AN synergistically [418]. At the same time, and at lower temperatures, some metal ammino complexes stabilize AN by shifting the temperatures at which troublesome phase transitions occur.

The solid-state reaction of AN and copper oxide was studied by the use of energy-dispersive and angle-dispersive XRD [419]. It was shown that the reaction takes place within the temperature interval 383–423 K (110–150 °C) and consists of two steps. The product of these consecutive reactions is the diammino copper complex. The relative concentrations of the species involved were determined by summing up different X-ray spectra. The resulting curves were analyzed by a computer program to obtain the kinetic constants of these reactions.

Copper(II) and zinc chromates intended as catalysts for AN decomposition can be prepared by co-precipitation and calcination. Copper(II) and zinc chromates were prepared by this method, and their catalytic activities for AN thermal decomposition were determined at 487 K (214 °C) [420]. The experimental kinetic data were interpreted in terms of a quantum cluster model calculation of the interaction of the spinel crystal structure with NH_4NO_3 and NH_3 . The activity of the spinel structure depends on the ratio of cation donor–acceptor properties and the capacity of the cations to participate in the electron density redistribution associated with the interaction with NH_4NO_3 or NH_3 .

The introduction of aluminum cations into $Cu_{1-x}Zn_xCr_{2-y}Al_yO_4$ catalysts drastically lowered their catalytic activity for AN decomposition [421]. The negative influence of aluminum cations on the catalytic properties of these catalysts was explained by quantum chemical computational analysis of the interaction between spinel clusters and AN. An increase of the presence of aluminum cations hinders the decomposition of AN because it increases the strength of proton bonding to the NH_4 group and

inhibits the first stage of decomposition of ammonium salts, which depends on proton transfer to the acid rest.

The effects of metal oxides, organic metal salts, energetic binders, and HNIW (CL-20) on the thermal decomposition of AN were studied using DSC and TGA-DTG [422]. Results showed that catalysts lower the endothermic decomposition temperature of AN to a certain extent, and energetic additives accelerate the exothermic decomposition process of AN.

Nanocomposites (nano-CuO and CuFe_2O_4) were characterized by powder XRD, transmission electron microscope, and XPS, and the catalytic performance of nano-CuO and CuFe_2O_4 on the thermal decomposition of AN was investigated using TGA/DSC and TGA/MS [423]. The results of TGA/DSC experiments indicated that nanocomposites catalyzed thermal decomposition of AN, especially copper oxide/graphene oxide. Copper iron oxide did not have a synergistic effect. The activation energy of AN mixture was calculated, and the initial onset temperature, peak temperature, and activation energy were significantly decreased. Nitrous oxide formed at a very low temperature, as observed by mass spectra. Two stages of thermal decomposition of AN catalyzed by copper oxide/graphene oxide were first observed with TGA/MS.

Metalorganic Catalysts for AN Decomposition

Ferrocene and similar metalorganic complexes are widely used as burning-rate catalysts for composite propellant and are effective catalysts for the decomposition of AN and AP, even in the absence of an organic binder. Similar catalytic effects are observed with metal complexes of 1,4,8,11-tetraaza[14]annulenes. The effect of various metal complex catalysts of tetraaza-(14)-anurene = tetraaza[14]annulene on the thermal decomposition of AN, AP, and a solid propellant containing AP as an oxidizer was studied using thermal analysis and burning-rate measurements. [424]. A metal complex that had iron or vanadium as the central metallic ion showed high activity during the thermal decomposition of AN. This activity was accelerated when chloride and perchlorate ions were present with iron or vanadium ions. Iron and vanadium catalysts also had high activity during the thermal decomposition of AP.

Supported PGM Catalysts for AN Decomposition

Methods for removing nitrates from natural and drinking waters include the catalytic decomposition of AN solutions on supported platinum group metal catalysts. This method may also be used for cleaning rinse waters from AN processing equipment before releasing the waste stream to surface waters or sewers. Supported platinum group metal catalysts for wet decomposition of AN were investigated in order to develop the catalysts, which can convert both ammonium ion and nitrate ion selectively to N_2 and H_2O under mild conditions, and to investigate the possible reaction pathways for simultaneous decomposition of ammonium and nitrate [425]. Pt/active car-

bon catalysts turned out to be the most active among the several catalysts examined; 2 mass-% Pt/active carbon decomposed AN effectively under 0.5 MPa of air at 453 K, showing a conversion of 99% or higher and N_2 selectivity of 95% or higher. N_2O was the main by-product with a selectivity of 5% or lower. Hardly any NO_2^- , NO, or NO_2 was observed. A series of experiments using isotope-labeled AN revealed that simultaneous removal of ammonium ion and nitrate ion did not take place via independent reactions of the two ions but rather via the equimolecular reaction between the two, and wet air oxidation of ammonium ion competed with the reaction of ammonium ion with nitrate ion. N_2O was the major intermediate of the reaction for all the reactions studied.

2.4.6.10 Inhibitors for the Decomposition of Ammonium Nitrate

Premature decomposition of AN during its manufacturing detracts from the nitrogen content, the fertilizer value, and the purity of the resulting product. It would be desirable to identify compounds (“anti-catalysts”) that would retard the thermal decomposition of AN under its manufacturing conditions. The rate of decomposition of AN at 498 K (225 °C) was investigated by determining the weight loss, the composition of the residue, and the change in pH for pure AN and simple mixtures containing AN and an additive [426]. The decomposition rate of pure AN climbed during the first 2 h until it reached 5.5% weight loss per hour of the original sample weight. The rate then dropped to about 2.5%/h. The pH of the salt decreased from 5.2 to 3.5 during the first 2 h of heating and then remained constant. The increase in acidity resulted in a corresponding increase in the rate of decomposition. Several amphoteric and basic oxides were added in an attempt to control pH. Alkali metal and ammonium bromides and iodides proved to be effective inhibitors when added in concentrations as low as 0.5%.

2.4.6.11 Slow Controlled Decomposition of Molten Ammonium Nitrate

Molten AN is self-decomposing, but the reaction may easily run away and result in an explosion. The differences in the reactions taking place in the vapor phase and in the condensed phase are difficult to explain under practical conditions. It is obvious that the mechanism depends on temperature and pressure. Most investigations were conducted only for a narrow pressure range; a few reports exist on the effect of pressure on the phase changes and decomposition processes.

Raman spectra of AN above its melting point of 443 K and decomposition temperature of 533 exhibited a strong peak at 1043 cm^{-1} , assigned to the ν_1 vibrational stretching mode of the NO_3^- group, and a 710 cm^{-1} peak attributed to the δ_4 bending mode of the NO_3^- group, whereas no peak was observed at approximately 940 cm^{-1} due to the $O'-NO_2$ stretching mode of HNO_3 [427]. Chemical equilibrium calculations based on the reaction $NO_3^- + NH_4^+ \rightleftharpoons HNO_3 + NH_3$ demonstrated that the concentration of HNO_3 gradually increases with temperature, although the HNO_3 to NO_3^- ratio

was still only approximately 0.0034, even at 533 K. Thus, molten AN was found to contain primarily NO_3^- and only a minor amount of liquid HNO_3 over the temperature range analyzed. The heat flow associated with condensed-phase decomposition was simulated based on the assumption that the decomposition rate of AN is given by

$$-dC_{\text{AN}}/dt = 10^{9.4} \exp(-125520/RT) C_{\text{NH}_4} + C_{\text{HNO}_3}$$

and that C_{NH_4} and C_{HNO_3} are constant due to chemical equilibrium. The heat-flow curves thus calculated were in good agreement with the experimental DSC data acquired at 5.1 MPa.

2.4.6.12 Mechanism and Reaction Sequences for Decomposition of Ammonium Nitrate

There are several reaction sequences depending on the temperature and pressure at which the reaction is allowed to proceed and the presence or absence of additives [139]. At temperatures just above its melting point, AN initially dissociates in reversal of its formation from ammonia and nitric acid, and it may sublime and recondense in colder parts of the system. This initiating step is a proton-transfer reaction:

Ammonia and nitric acid can be identified above 453 K (180 °C) in the gas phase during rapid-scan FTIR thermal profiling [428]. At higher temperatures, between 483 and 563 K (210 and 290 °C), the slow irreversible decomposition would lead to a mixture of nitrous oxide and water:

This is actually one of several methods for the production of nitrous oxide. This is a dangerous reaction, and, unfortunately, several factories performing this reaction have blown up. This is a first-order reaction, and the activation energy is about 159 kJ/mol (38 kcal/mol) [429]. Side reactions make the interpretation of kinetic measurements more difficult [430].

The rapid pyrolysis chemistry of thin films of AN and ADN at temperatures approximating a burning surface was studied using T-jump/FTIR spectroscopy [431]. It is quite valuable to study these two oxidizers next to each other using the same equipment because AN is one of the intermediate decomposition products of ADN. The sequence of appearance and amounts of each gas product combined with the net endothermicity and exothermicity of the process at each point in time gave the necessary information to develop multi-step reaction schemes. The decomposition of the condensed phase of AN is net endothermic up to at least 3.33 MPa (33 atm). Although

dissociative sublimation and the formation of N_2O and H_2O dominate the overall process, the superposition of two additional reactions is needed to account for all of the products observed from AN. The spectra and thermal responses are consistent with the assumption that the reaction of NH_3 with NO_2 is the major source of heat released during the decomposition of AN above 3.33 MPa (33 atm).

Based on the species detected in the mass spectrogram of a dynamic flow reactor, the following equations were proposed to describe the decomposition of AN (Table 25; [432]).

Table 25: Balanced equations for decomposition reactions of AN.

Equa- tion no.	Balanced equation	Enthalpy of reaction, kJ/mol	Entropy of reaction, $\text{J mol}^{-1} \text{K}^{-1}$	Adia- batic temp, °C
1	$2\text{NH}_4\text{NO}_3(\text{S}) \rightarrow \text{O}_2(\text{G}) + 4\text{H}_2\text{O}(\text{G}) + 2\text{N}_2(\text{G})$	-118.1	521	970
2	$\text{NH}_4\text{NO}_3(\text{S}) \rightarrow 2\text{N}_2\text{O}(\text{G}) + 2\text{H}_2\text{O}(\text{G})$	-36.5	446	345
3	$2\text{NH}_4\text{NO}_3(\text{S}) \rightarrow 2\text{NO}(\text{G}) + 4\text{H}_2\text{O}(\text{G}) + \text{N}_2(\text{G})$	-26.8	533	261
4	$2\text{NH}_4\text{NO}_3(\text{S}) \rightarrow \text{NO}_2(\text{G}) + 4\text{H}_2\text{O}(\text{G}) + 1.5\text{N}_2(\text{G})$	-100.9	490	848
5	$1.5\text{NH}_4\text{NO}_3(\text{S}) \rightarrow \text{HNO}_2(\text{G}) + 2.5\text{H}_2\text{O}(\text{G}) + \text{N}_2(\text{G})$	-89.8	461	754
6	$2.5\text{NH}_4\text{NO}_3(\text{S}) \rightarrow \text{HNO}_3(\text{G}) + 4.5\text{H}_2\text{O}(\text{G}) + 2\text{N}_2(\text{G})$	-123.3	257	989
7	$\text{NH}_4\text{NO}_3(\text{S}) \rightarrow \text{HNO}_3(\text{G}) + \text{NH}_3(\text{G})$	+185.5	94	

Data source: [432]

The results can be compared to those obtained for hydroxylammonium nitrate and ammonium dinitramide decomposition. In both cases, nitric acid formation competes with oxygen formation. Based on equilibrium calculations using HSC Gibbs, nitric acid is a very stable intermediate kinetic product up to about 523 K (250 °C). Above 573 K (300 °C), HNO_3 decomposes into H_2O and NO_2 .

An excellent summary of the role of additives in the combustion of AN was published by Sinditskii et al. [433] in 2007. Another study evaluated processes that take place in the condensed phase during combustion of AN. The AN decomposition begins with a proton transfer, with the formation of NH_3 and HNO_3 dissolved in the condensed phase. This is followed by thermal decomposition of nitric acid. It was shown by direct experiments that the rate of HNO_3 consumption was higher in the presence of NH_4^+ ions than the thermal decomposition of pure nitric acid [434, 435]. The increase in the HNO_3 consumption rate was directly proportional to the NH_4^+ concentration. It was assumed that the kinetics of this reaction could be described by interaction of NH_4^+ ions not only with HNO_3 molecules but also with N_2O_5 molecules. N_2O_5 is the anhydride of nitric acid but is not very stable.

Known amounts of water, ammonia, or nitric acid were added in various combinations to a stream of entraining helium gas to determine their effects on the rate of AN decomposition in the molten state [436, 437]. Water and ammonia inhibited the re-

action, and nitric acid catalyzed it. The water effect reported here is contrary to other observations that carefully dried AN does not decompose below 573 K (300 °C).

This sequence explains the observable behavior of liquid-phase AN decomposition very well: Acidic species increase the rate of AN decomposition dramatically, whereas bases such as ammonia and water retard decomposition. For a high-dipole environment, as in a solvent of molten AN, the existence of an ionic structure such as $\text{NO}_2^+ \text{NO}_3^-$ is quite acceptable, although its covalent but less stable isomer N_2O_5 also plays a role in the overall process of AN decomposition. See also [438].

At higher and higher temperatures, the ionic mechanism of AN decomposition is replaced by reactions involving free radicals, with homolysis of nitric acid being the rate-controlling step:

The end result of AN decomposition is the same for both modes of decomposition:

Parallel to the main decomposition reaction, several side reactions can take place:

Intermediate steps in these reactions involve the following reactions:

N-isotope and O-isotope substitution has been used to resolve questions about the origin of the N-atoms in the formation of N_2O by decomposition of AN [206]. The decomposition products of $^{15}\text{NH}_4\text{NO}_3$ were analyzed for isotope effects both during the course of the reaction and at complete decomposition. An authentic sample of $^{15}\text{N}^{14}\text{N}^{16}\text{O}$ was prepared that contained ^{15}N exclusively in the end position, characterized by IR spectra, and was used for comparison to N_2O samples obtained in the course of this study. It was found that small amounts of water are necessary to initiate the decomposition of AN. $^{15}\text{NH}_4\text{NO}_3$ has been found to yield exclusively the

isomer $^{15}\text{N}^{14}\text{NO}$. Some inferences can be drawn from this observation regarding the mechanism of the reaction. Oxygen and nitrogen isotope effects accompanying the decomposition have been compared to results obtained with material of “natural” isotopic composition. Satisfactory agreement was found between the experimental results and theoretical calculations. Other species that have been hypothesized as intermediates in AN decomposition include nitrosamine $\text{ON}-\text{NH}_2$, nitramine $\text{O}_2\text{N}-\text{NH}_2$, and hyponitrous acid $\text{HO}-\text{N}=\text{N}-\text{OH}$.

There are several experimental techniques for investigating the rate of decomposition of AN and the strand burning of AN. All require exact knowledge of the temperature of the bulk sample, the flame front, and the decomposition products. It is important to use thermocouples made from materials that do not catalyze the decomposition of AN and do not catalyze the combustion of NH_3 in HNO_3 . The validity of some published temperature-measurement data has been questioned because of alleged catalytic thermocouple-sample interactions.

The onset of thermal decomposition and the rate of heat evolution during storage of bulk AN are greatly affected by the type and quantity of contaminants commonly found in industrial grades of AN [439]. In the wake of the Texas City (1947) and Toulouse (2001) disasters and other explosive events, the effect of impurities on the rate of AN decomposition has been thoroughly investigated.

An experimental and modeling study was aimed at a better understanding of the impact of the operating conditions on the interplay between AN decomposition pathways and their coupling with gas-phase chemistry and the role of operating conditions on AN thermal decomposition [440]. A condensed-phase semi-detailed kinetic mechanism was developed and validated against new data and reported data from other groups. This mechanism was coupled to a gas-phase mechanism, making it possible to quantify the contributions of condensed-phase and gas-phase reaction pathways to AN thermal decomposition at different heating rates. At typical burning surface temperatures (523 K [350 °C]), gas-phase reactions involving nitramide and nitric acid play a significant role.

A series of TGA experiments with AN was conducted with four different heating rates to obtain the accurate kinetic parameters of AN thermal decomposition in air [441]. The activation energies of AN pyrolysis were calculated by different isoconversional methods. The value of E_{act} was stable near 93 kJ/mol in the conversion range of $\alpha = 0.1 - 0.96$, which means the reaction obeying the single-stage character of the irreversible process can be represented by model-free approaches. The expression of the optimal kinetic mechanism model for four heating rates was

$$f(\alpha) = \alpha^{-0.0259}(1 - \alpha)^{0.0617}$$

2.4.6.13 Effect of Pressure on Decomposition of Ammonium Nitrate

An accelerating rate calorimeter was used to study the decomposition of AN under 0.1–3 MPa helium pressure [442]. Gas chromatography and MS analysis of the gaseous

products indicated that the decomposition proceeds by the same mechanistic pathway up to 3 MPa applied pressure. Kinetic fitting of the ARC data was done using the BatchCAD package. There was good agreement between the predicted and experimental values. For the first time, independent Arrhenius parameters for two parallel reactions for AN decomposition were reported, with different E_a and A values in the two kinetic equations.

The influence of pressure on phase transitions, melting, and thermal decomposition characteristics of pure AN was measured using PDSC under ambient pressure conditions and up to a maximum pressure of 6.868 MPa (68 atm) [87]. A sample of four DSC thermograms for four different pressures was already shown in Figure 2. The temperatures of the onset of decomposition were distinctly shifted with increasing pressure (Table 26). At the highest pressure, the decomposition created a strong exotherm, starting at 583 K (310 °C) and peaking at 586.6 K (313.5 °C).

Table 26: Effect of pressure on onset of decomposition temperature of ammonium nitrate.

Sample no.	Pressure		Decomposition onset temperature	
	MPa	atm	K	°C
1.	0.101	1	481.75	208.6
2.	1.379	13.61	487.44	214.29
3.	2.068	20.41	584.99	311.84
4.	2.757	27.21	541.69	268.54
5.	4.136	40.82	532.25	259.10
6.	5.514	54.42	546.46	273.31
7.	6.893	68.03	583.30	310.15

2.4.6.14 Kinetics of Decomposition of Ammonium Nitrate

The decomposition kinetics of liquid AN can be described by a first-order equation of autocatalysis. The temperature dependence of the rate constants is as follows:

$$k_1 = 10^{14.4} \exp(-23754/T), \quad \text{s}^{-1}$$

$$k_2 = 10^{7.3} \exp(-5736/T), \quad \text{s}^{-1}$$

The decomposition at temperatures near 473 K (200 °C) has often seemed to show variable induction periods and capricious variations in rate. It has been reported, for example, that completely dry AN does not decompose below 473 K (200 °C). On the other hand, there are clear indications that water inhibits the decomposition. In view of conclusions made by some investigators [384] about ionic and radical mechanisms of AN decomposition, it was proposed that k_1 describes the radical decomposition pathway,

with an activation energy corresponding to $\text{HO}-\text{NO}_2$ bond scission, and k_2 describes the low-temperature ionic pathway of decomposition. In these experiments, the rates of decomposition of AN in the liquid and vapor states were measured at temperatures up to 673 K (400 °C). Samples of absolutely dry AN were sealed in glass capillary tubes and immersed in a molten metal bath for varying lengths of time. The capillaries were quenched, and the gas evolved was captured and analyzed. The liquid remaining after complete decomposition was analyzed using ion chromatography. Nitrate ion was the only anion found. The quantity of nitric acid was determined by electrical conductivity. The data were fitted into Arrhenius plots and indicated that an ionic mechanism predominating at temperatures below 563 K (290 °C) is overtaken by a homolytic mechanism at higher temperatures. The low-temperature activation energy of 118 kJ/mol is somewhat lower than other reported values. With higher operating temperatures, the activation energy increased to 193 kJ/mol, which is nearly equal to the N—O bond energy in HNO_3 and the enthalpy of reaction for homolysis of HNO_3 into $\cdot\text{OH}$ and $\cdot\text{NO}_2$. Water and NH_3 strongly inhibit the ionic reaction at low temperature, but the effect diminishes at high temperature. Based on experiments with ND_4NO_3 , there is no primary H/D kinetic isotope effect. The primary reaction pathways predict that there should be no H/D kinetic isotope effect, but other schemes might involve abstraction of hydrogen from ammonia in the rate-determining step. The rate of decomposition of NH_4NO_3 and ND_4NO_3 was measured at 613 K (340 °C), and an isotope effect of 1.2 was found. This may have been due to secondary dissociation of $\text{DO}-\text{NO}_2$. The reaction rates of liquid and vapor were nearly the same at high temperature.

The introduction of Cl^- ions into AN increases both the initial rate of decomposition (k_1) and the rate of self-acceleration (k_2), with the latter growing much faster than the former (Section 2.4.6.8). Thus, the introduction of only 0.5% Cl^- leads to a 5-fold increase in k_1 and a 30-fold increase in k_2 at 473 K (200 °C). The greater increase in the degree of self-acceleration results in reduction of the activation energy of the leading combustion reaction of catalyzed AN.

Estimates based on fitting data to single-step kinetic models tend to be misleading, especially when these estimates are obtained from non-isothermal measurements. As an alternative, one may use model-free isoconversional methods that allow for reliably estimating the activation energy as a function of the extent of conversion. Both model-fitting and model-free computational techniques were applied to the thermal conversion of AN under isothermal and non-isothermal conditions as measured by TGA [443]. The model-fitting method to the isothermal data demonstrated that both solid-phase and liquid-phase kinetics are characterized by a single activation energy of 90 kJ/mol. In parallel, a model-free isoconversional method was applied to isothermal and non-isothermal data and yielded an almost identical activation energy, which is essentially independent of the extent of conversion. In both phases, the process can be described by the activation energy of ~ 90 kJ/mol and by a pre-exponential factor of around 10^9 min^{-1} . These kinetic characteristics are assigned to the process of dissociative sublimation/vaporization.

The thermal gasification of AN demonstrates similar kinetics in the solid and liquid phases. The Arrhenius plot of the gasification of AN is shown in Figure 25.

Figure 25: Arrhenius plot for the isothermal gasification of solid and liquid AN. (Reprinted and modified from [443], with permission from © 2001 American Chemical Society; permission conveyed through RightsLink.)

The majority of AN decomposition studies worked with molten AN. There are only a few studies that worked at higher heat fluxes such that solid AN would immediately transition to the vapor phase. The rate of AN decomposition also depends on the composition of the atmosphere surrounding the reacting sample. The decomposition takes different routes if the decomposition products are trapped near the sample (static) or if they are purged away by a stream of inert gas (dynamic).

Making use of labeled nitrogen in the AN decomposition reaction, it has been shown that the principal decomposition product N_2O is formed from NH_4^+ and NO_3^- ions (one atom of nitrogen from each ion). This led some investigators to postulate direct bimolecular interaction of the NH_4^+ and NO_3^- ions or molecular decomposition of NH_4NO_3 into the end products. Certain investigators emphasize the important role of the nitric acid formed during the thermal decomposition of AN. In this case, the acceleration of decomposition is associated with interaction of the NO_2^+ ions and the NH_4NO_3 entering the reaction.

The decomposition of AN is carried out on an industrial scale for the production of nitrous oxide. This is a very hazardous operation, and several factories have been destroyed by explosions in the process. To reduce the explosion hazard, it has been attempted to dilute the AN melt with other fused salts in which the AN dissolves [444].

2.4.6.15 Fast Controlled Decomposition of Ammonium Nitrate

Ammonium nitrate as oxidizer in a solid propellant or gas generant decomposes rapidly as soon as the flame front has worked its way to the oxidizer granules. The fast decomposition of AN obeys different kinetics than the slow decomposition of AN. One of the common methods to study fast decomposition is to place the AN crystals on a platinum ribbon and pass an electric current through the ribbon so that it glows like a light bulb filament. Diagnostics can then be done on the volatilized products by absorption spectroscopy or mass spectrometry.

Fast thermolysis studies of AN and its mixtures with Mg or activated charcoal have been carried out using an FTIR/temperature profiling technique [445]. When subjected to rapid heating (about 80 °C/s), AN sublimed/decomposed at around 573 K (300 °C). Sublimation dominated at ambient pressures. The IR-active products of decomposition were NH_3 , NO_2 , N_2O , and H_2O . One of the first steps of reaction is most likely a proton transfer leading to NH_3 and the decomposition products of HNO_3 . The decomposition of AN was significantly enhanced when AN was mixed with Mg powder or charcoal, and it may occur at temperatures as low as 408 K (135 °C). Whereas NH_3 was the major product of decomposition of AN/Mg mixtures, no NH_3 was observed from AN/C mixtures. The different behavior of AN in these mixtures may be the result of reactions of AN with Mg or C.

Sputtering of condensed-phase AN at the inlet to a mass spectrometer yields many positive and negative cluster ion series derived from different ionic cores [446]. The cluster cores are surrounded by varying numbers of AN monomer units, such as $[(\text{NH}_4\text{NO}_3)_n\text{NO}_3]^-$, $n \geq 3$ or $[(\text{NH}_4\text{NO}_3)_n\text{NH}_4]^+$. Collision-induced dissociation of mass-selected cluster ions suggests that the first two members of the negative series, $n = 1$ and $n = 2$, are not detected because they rearrange and lose one or more ammonia molecules. NH_4NO_3 is strongly hydrogen bonded, but $[(\text{NH}_4\text{NO}_3)\text{NO}_3]^-$ has no hydrogen bonds. This is consistent with this ion rearranging by loss of NH_3 to form the strongly hydrogen-bonded ion $[\text{H}(\text{NO}_3)_2]^-$.

Rapid Decomposition of Gasified Ammonium Nitrate

Experiments were conducted in which the surface of solid AN was heated at such a high rate of heat input that the surface gasified at a rate much higher than the bulk decomposition rate [447]. Under these conditions, the surface gasification proceeded by a mechanism that was characterized by a small activation energy (29.3 kJ/mol = 7 kcal/mol) and produced essentially only HNO_3 and NH_3 as the primary products. There may actually be some surface superheating beyond the equilibrium condition.

The experimental linear pyrolysis rates of AN strands between 452 and 573 K (180 and 300 °C) can be expressed in good approximation by the equation

$$B = 120 \exp(-7100/RT_s)$$

where B is the regression rate in cm/s, T_s is the surface temperature in kelvin, and R is the gas constant. The linear pyrolysis of AN is a very endothermic event. Figure 26 shows the linear pyrolysis rate of AN (on a logarithmic scale) as a function of the reciprocal surface temperature.

Figure 26: Linear pyrolysis rate of AN as a function of the reciprocal surface temperature. (Republished and modified from [447], with permission of American Institute of Aeronautics Astronautics; permission conveyed through Copyright Clearance Center, Inc.)

Below 453 K (180 °C) the pyrolysis rate dropped sharply and became essentially independent of temperature. It was suggested that this drop is related to melting process rather than a sublimation process. One of the less volatile species that remains adsorbed to the melting AN is nitric acid. The heat of vaporization of HNO_3 is of the same magnitude as the energy of activation for rapid pyrolysis of AN, suggesting that the desorption of HNO_3 is the rate-controlling step. The heat of fusion of AN is 6.1 kJ/mol (1.460 kcal/mol) and is less likely to be rate controlling.

Investigators developing a model for the combustion of AN composite propellants pointed to the leading role of AN gas-phase reactions [447–449] and postulated that AN gasifies first at about 600 K by an endothermic reaction to form ammonia and nitric acid. These gaseous products then undergo exothermic redox reactions near the surface to establish a flame front of about 1250 K, which radiates and conveys heat that drives the gasification of AN and pyrolysis of the binder.

In contrast to that, it was postulated by Kondrikov et al. (1998) [450] that the leading reaction in combustion of AN-based compositions takes place mostly in the condensed phase up to pressures of the order of hundreds of atmospheres. They studied the critical burning conditions of three categories of AN-based compositions: neat AN with minor additives to lower the pressure deflagration limit, a composition based on AN/TNT 80/20 mixtures, and materials containing RDX or liquid nitric esters. It was shown that combustion of almost all the substances studied can be characterized by steady burning rates and dependence of the burning rates on pressure, but at the same time it is connected with the very low levels of burning stability at lower pressures: The pressure deflagration limit and the critical diameter of burning in the majority of cases were much higher than the corresponding values observed for the standard double base and composite propellants as well as for the variety of nitro compounds investigated earlier.

Mass spectrometry and IR spectrophotometry are the two prime fast-response methods used to analyze transient phenomena occurring on the surface of decomposing energetic materials. These methods can be applied to oxidizers by themselves, to formulated solid propellants, or to slabs of oxidizer sandwiched between two layers of fuel binder. The methods for rapid heating in either case can be a laser pyrolysis or thin-film sample heating on a rapidly heated metal ribbon (T-jump/FTIR spectroscopy).

A different chemical mechanism of combustion of AN-based composites has been offered, in which the main reason for the inability of AN and mixtures to burn at low pressures was supposed to be the presence of a large amount of water in the reaction layer as a product of AN decomposition, which of course extinguished combustion by decreasing reaction rate and surface temperature [451]. The role of catalysts in this combustion mechanism is to enhance the rate of AN decomposition, which, in turn, results in water removal from the reaction mixture. On the other hand, combustion of water-impregnated AN-based explosives showed that the presence of 15–22% water in the compositions did not hinder sustained burning.

2.5 Strand-Burning Rates of Ammonium Nitrate

Strand burning of AN by itself (without addition of binders or combustibles) was studied to better understand the mechanism of AN combustion and to study the effect of burning-rate modifying additives without interference by combusting fuels. However, according to Glazkova [452], neat AN does not burn in glass tubes of large diameter (30 mm), not even at 100 MPa. In other studies [433, 453, 454], AN in the molten state was found to be incapable of burning in tubes with a 7-mm diameter at atmospheric pressure. Results at pressures up to 20–30 MPa indicated that the leading reaction of combustion of AN doped with additives proceeds in the condensed phase. An addition of small amounts of some catalytic mineral substances to AN is required to burn AN without a fuel, but the role of additives in the combustion mechanism is difficult to explain. It is known that the addition of chlorides results in a decrease in AN stability, shifting the temperature of the onset of exotherm from 599 to 519 K (326 to 246 °C) for a mixture with 5% KCl. One proposed mechanism of additive action is to promote heat generation in the condensed phase, which stabilizes combustion and raises decomposition rate. The AN flame consists of separate flame zones and remains at some distance off of the surface at pressures below 20 MPa. This distance decreases with increased pressure, and the flame settles onto the surface at 20–25 MPa (i.e., when the burning rate vs. pressure curve also undergoes a break). It is interesting to compare the peculiar behavior of AN deflagration with that of other ammonium salt oxidizers, such as ADN and AP [455]. Based on numerous thermocouple-aided experimental studies on the combustion of different energetic oxidizers, it has been shown that a material in the condensed phase can be heated up to its boiling point or, in the case of salts, to their dissociation temperatures. In contrast to the gas-phase model, the condensed-phase model has an energy limitation. Since in condensed-phase reactions the burning rate increases at the expense of surface temperature increase with pressure, there can be a situation when the heat effect of energetic material decomposition is no longer sufficient for warming-up the substance to the surface temperature. This induces an instability of combustion and burning-rate oscillations [456, 457]. See also [458, 459].

2.5.1 Additives for Strand Burning of Ammonium Nitrate

Because the strand-burning rate of AN by itself and in combination with fuels in solid propellants is relatively slow (in comparison to those of AP propellants), a significant amount of effort has been devoted to find additives to increase the burning rate for AN [460]. Ideally, such additives should not only increase the burning rate but also eliminate the nasty phase transitions of AN at the same time.

Pellets of cast instead of tamped or pressed AN/HN and HN were used in a study of surface temperatures of burning solid propellants. The HN and HN-AN eutectics were used as model substances because the melt surface gives a well-defined surface

temperature. Both 32 mol-% AN/68 mol-% HN (melting point 316 K) and HN castings had to be catalyzed with 1.5 mass-% Cr_2O_3 catalyst, which was mixed in at temperatures a few degrees above the melting point before the cylinders were allowed to solidify in glass tubes as molds. A series of thermocouples was embedded in the cast grain, which recorded the passing of the combustion front. The temperature would level off while the melted zone was passing through. Burn rates of 0.25–0.78 cm/s at 0.68–5.35 MPa were typical for catalyzed AN-HN, whereas catalyzed HN would burn much faster, 1.2 cm/s at 41 bar. The average surface temperature of burning AN-HN was 580 K vs. 468 K for HN by itself.

The effects of additives on the rate of deflagration of AN and AP were summarized in a book by Glazkova [461]. The effect of catalysts such as 4.9% NaCl and NH_4Cl can be enhanced further by addition of promoters [462]. Some promoters can enhance the burning-rate-increasing effect of catalysts by a factor of 1.5–3.

An excellent summary of the role of additives in the combustion of AN was published by Sinditskii and co-authors [433, 453, 463]. It was determined that the surface temperature of AN is controlled by the dissociation reaction of the salt occurring at the surface. Results obtained from experimental analysis have indicated that the leading reaction of combustion of AN doped with additives proceeds in the condensed phase up to pressures of 20–30 MPa. It is surprising that many inorganic mineral additives to AN increased the rate and completeness of burning of both the pure salt and reactive oxidizer/fuel compositions. Thus, an addition of 7 mass-% of sodium chloride to AN makes sustained burning possible at and above 1.2 MPa (Figure 27). The particle size of the additives was less than 100 μm . Additives of other chlorides of alkaline and alkaline-earth metals had a similar effect. Generally, the curve of burning rate (r_b) vs. pressure (p) demonstrated a break (change of slope) at 20–25 MPa, with a strong pressure influence on the burning rate before the break (the pressure exponent, $n = 0.9 - 0.95$) and a weaker dependence above it ($n = 0.5 - 0.6$).

Many investigators have attempted to explain the effect of halide ion addition on AN burning. It is known that the addition of chlorides results in a decrease in AN stability, shifting the onset of AN exotherm from 599 K (326 °C) to 519 K (246 °C) for a mixture containing 5% KCl and 95% AN [464]. The mechanism of influence of halide ions is not completely understood. Many researchers, e.g., Rubtsov et al. [465], have pointed to a synergism in the action of HNO_3 and Cl^- and tried to explain the presence of an induction period observed by Colvin et al. [466]. They suggested that the key reaction in the catalysis of AN decomposition by chloride ions involves the intermediate formation of nitryl chloride:

Atomic chlorine, a free radical, is a very reactive species and may participate in several critical decomposition steps. The rate-controlling step of these processes could be the hydrogen atom abstraction from ammonia under the action of a chlorine atom. The subsequent reactions of $\bullet\text{NH}_2$ radical with NO_2 and NO proceed quickly. This mecha-

Figure 27: Pressure dependence of the burning rate of AN with addition of 7% NaCl (● circles), 8.5% BaCl₂ (+ crosses), or 5% NaF (▼ triangles). (Reprinted and modified from [433], with permission from © 2007 Begell House, Inc.)

nism casts some doubt on a conclusion made by Brower et al. that formation of NO₂⁺ is the rate-limiting step in the ionic mechanism of AN decomposition. Other halides, bromides and iodides, act in a similar way. In contrast to chlorides, bromides, and iodides, the fluorides inhibit AN decomposition rather than catalyze it. Another intermediate postulated in the chloride-catalyzed decomposition of AN is chloramine ClNH₂.

Amatol is a mixture of AN and TNT and burns more readily than AN by itself. The effect of partial substitution of AN in amatol 80/20 by alkali metal salts on the strand-burning rates of amatol was measured at high pressures [467]. There are two ways of retarding the chemical reactions involved in the combustion of AN and its mixtures: One is the addition of compounds that readily release ammonia, thus shifting the AN dissociation equilibrium to the left. The other is the addition of reducing agents, which sequester the HNO₃ and thus slow down the oxidation of NH₃. In 7-mm plexiglass tubes, the amatol mass consumption rate at 145–1000 atm can be expressed by the equation

$$U_b = -0.58 + 0.00554P$$

where U_b is the mass consumption rate in $\text{g cm}^{-2} \text{s}^{-1}$ and P is the pressure in atm. Addition of ammonium oxalate or iron oxalate decreased the burning rate, while sodium oxalate or potassium oxalate increased the burning rate. Potassium fluoride increased the burning rate even more significantly.

There will be substantially more information on the effect of burning-rate modifying additives in AN/binder solid propellant compositions in future volumes of the *Encyclopedia of Rocket Propellants*, and a brief introductory discussion is given in the following section.

2.5.2 Combustion of Ammonium Nitrate in Rocket Propellants

There are numerous publications on the combustion of AN in rocket propellants and gas generants. Here we have discussed some related papers in which the emphasis is on the kinetics of AN decomposition as an oxygen source and on the effects of AN particle size and additives on the burning rates of such propellants.

The combustion of AN and energetic mixtures containing AN were examined based on combustion and deflagration chemical and thermal decomposition mechanisms and compared to results obtained with AP in similar experiments [468]. The main features of AN thermal decomposition compared with AP decomposition are as follows: **(1)** The salt decomposes in the liquid phase during combustion, **(2)** the concentration of acid formed in the liquid phase, as a result of dissociation equilibrium, is greater because HNO_3 is a weaker acid than HClO_4 , **(3)** the volatility of NH_4NO_3 is higher and the temperature of the burning surface is lower, and **(4)** the oxidizing ability of AN decomposition products is weaker than that of AP. The combustion of AN-based propellant compositions can be explained in terms of the mechanism in which the decomposition in the condensed phase plays a major role, with additional influence exerted by gas-phase reactions. Similar observations have been made with other ammonium salts and are characteristic for most ammonium salts (including hydrazinium nitrate).

Excellent summaries of decomposition kinetics of AN and other oxidizers and energetic materials in the combustion wave were compiled by Sinditskii and co-authors [469, 470]. Experimental data on burning rates and surface temperatures have allowed us to derive unique information on the decomposition kinetics of energetic materials at high temperatures, provided that combustion of these materials occurs in the condensed phase. Kinetic parameters of the leading reaction on combustion of AN were compared to those of three other solid rocket propellant oxidizers: AP, ADN, and HNF, as well as six energetic fillers.

The surface temperature in the combustion wave of AN, as well as in ADN, HNF, and AP, is controlled by a dissociation process similar to that postulated for other onium salts [471].

2.5.3 Combustion of Activated Charcoal in Ammonium Nitrate

Activated charcoal (AC) is not a typical rocket fuel, but the combination of AN and AC would make a potential rocket propellant or explosive, and carbon black is very cheap. Charcoal has very simple combustion mechanics and creates only two combustion products. Surprisingly, activated charcoal has a very strong catalytic effect on the decomposition of AN. This may be different from the effect of graphite, which is sometimes added as an opacifier or applied as a coating to make the surface of solid propellant grains electrically conductive to prevent buildup of electrostatic charges.

We are not quite sure if we should list carbon black (CB) as a combustible additive or as a catalyst. The true designation of a catalyst is that it is not consumed in the reaction, but carbon black is altered in the decomposition of AN and eventually consumed once the mixture ignites. Therefore, we list carbon black as an additive and not as a catalyst.

In the presence of carbon black, the decomposition rate of solid AN in the temperature range 343–423 K (70–150 °C) was shown to increase by more than seven orders of magnitude [472]. At relatively low temperatures, the process proceeded by a two-stage mechanism, with corresponding acceleration at each stage. At elevated temperatures, the first stage was absent, and the reaction went directly into high gear. The decomposition rate was proportional to the amount of carbon black in the mixture. The activation energy for the decomposition (≈ 125 kJ/mol = ≈ 30 kcal/mol) did not vary during transformation. Water decelerated the process. For a water content of 4–5%, an intermediate maximum of the deceleration was observed. The main gaseous decomposition product was N_2 . In a stoichiometric mixture, carbon black is oxidized to CO_2 :

The strong increase in the rate of thermal decomposition of AN under the action of carbon black is probably due to the fact that HNO_3 formed in this reaction is rapidly reduced by carbon black to HNO_2 and its anhydride N_2O_3 , which are, in turn, active nitrosation agents with respect to NH_3 and NH_4^+ , enhancing their transformation to N_2 . The ordinary thermal decomposition of HNO_3 , as shown by its kinetics, cannot yield the necessary rates even at the highest possible concentrations of the acid corresponding to the achievable depth of AN conversion in a mixture with CB.

Raman spectroscopic analysis, DSC, TG-DTA-IR, TG-MS, and flash pyrolysis MS were carried out to study the influence of the physical properties of different types of carbon on the thermal decomposition behavior of AN/carbon mixtures [473]. As seen in DSC thermograms, AN mixed with activated carbon or carbon nanotubes exhibited violent reactions after the melting of AN, while AN mixed with graphite or fullerene showed only mild exothermic peaks, the same as for pure AN. Diamonds were not tested for lack of free samples. From the TG-IR results, CO_2 formation was more pronounced for AN and activated carbon and for AN and carbon nanotube mixtures than for other mixtures. It was concluded that AN mixed with carbon of low crystallinity showed violent reactions after melting, while AN mixed with carbon of

high crystallinity showed the same behavior as pure AN. The thermal decomposition behavior of AN/carbon mixtures was not influenced by the crystallinity of carbon when flash-heated rapidly and instantaneously. Ammonium nitrate mixed with carbon, such as graphite, did not burn below 7 MPa. Compositions with more than stoichiometric amounts of activated carbon had higher burning rates. The burning rate of AN/AC mixed with CuO as a combustion catalyst deteriorated faster than if additive-free [474].

In order to obtain a better understanding of combustion and ignition properties of AN or PSAN and activated carbon (AC) mixtures, friction sensitivity tests, thermal analysis, and 200-mL closed-vessel combustion tests were carried out, and the influence of the mixture ratio on the combustion and ignition properties of various AN/AC mixtures was investigated [475–478]. In the differential scanning calorimeter, AN mixed with more than 4 mass-% of AC mixtures showed a violent exotherm after the melting of AN, and some of the mixtures exploded. In the 200-mL closed-vessel test, the maximum rate of pressure rise was observed at a higher AN concentration than the stoichiometric composition.

The effects of copper(II) oxide on the thermal decomposition of AN mixtures and the thermal characteristics of AN, carbon, and CuO mixtures were measured using simultaneous DSC and TGA-DTA connected with IR spectroscopy and MS [479]. In the TGA-DTA results for AN/AC/CuO and AN/CB/CuO mixtures in an open cell, an exotherm was observed at approximately 483 and 503 K (210 and 230 °C), respectively. In addition, the IR and mass spectra of the gases produced from the AN/AC/CuO and AN/CB/CuO mixtures indicated the presence of CO₂. These results suggest that the effect of CuO on the oxidation of different types of carbon depends on the chemical reactivity of the carbon, which is derived from its physical properties.

A thermal analysis using DSC of the decomposition of AN with activated charcoal (carbonized rice husks) or dextran showed a tendency of lowering of the activation energy of the oxidizer in the presence of dextran [480]. The calculated activation energies were in the range of 65–82 kJ/mol. The combustion wave behavior was studied in a windowed high-pressure chamber and recorded by a high-speed camera.

2.6 Safe Handling of Ammonium Nitrate

2.6.1 Materials for Construction, Compatibility, and Corrosion of Ammonium Nitrate

2.6.1.1 Compatibility of AN with the Environment

Ammonium nitrate comes in contact with the environment in packaging materials, shipping containers, mixing equipment, and rocket/gas generator combustion chambers prior to ignition. These conditions are relatively easy to control, and materials are selected that are known to be compatible.

For AN used in blasting agents, the downhole conditions are less well known or predictable and may involve minerals that AN is not compatible with. A frequent

mineral encountered in coal seams or rock quarries is pyrite. Pyrite is not likely to be encountered in rocket propellants, but we include these data here nevertheless. The effect of pyrite on AN decomposition had to be studied to prevent premature ignition of ANFO pumped into drill holes. The reaction of AN with pyrite was studied using a simultaneous differential scanning calorimeter and thermogravimetric analyzer (TGA/DSC) [481, 482]. When a mixture of pyrite and AN is heated at a constant heating rate from room temperature to 1073 K, two exothermic reactions occur at about 473 and 723 K, respectively. The first exothermic reaction is considered to take place between AN and pyrite, where NO, NH₃, SO₂, and N₂O gases are produced. The second exothermic reaction is due to the oxidation of the remaining pyrite by atmospheric oxygen. Based on the quantitative analysis of the gaseous and solid products of the reaction, a new overall reaction was proposed at the first exothermic peak of interest, which is thermodynamically favorable. The results have significant implications for the understanding of the stability of AN-based industrial blasting agents in reactive mining grounds containing pyritic minerals. The activation energy and the pre-exponential factor of AN decomposition were determined to be 102.6 kJ/mol and $4.55 \times 10^7 \text{ s}^{-1}$ without the presence of pyrite and 101.8 kJ/mol and $2.57 \times 10^9 \text{ s}^{-1}$ with the presence of pyrite. The kinetics of AN decomposition was then used to calculate the critical temperatures for AN decomposition with and without the presence of pyrite, based on the Frank-Kamenetskii model of thermal explosion. It was shown that the presence of pyrite reduces the temperature for, and accelerates the rate of, decomposition of AN, causing dangerous premature detonation of the explosives.

2.7 Transportation, Storage, and Disposal of Ammonium Nitrate

2.7.1 Transportation of Ammonium Nitrate

There are two main grades of AN, fertilizer grade (FGAN) and technical grade (TGAN). The two are chemically identical. TGAN formulations are more porous than FGAN to facilitate the absorption of fuel for use in explosives (e.g., ANFO). As the name suggests, fertilizer grade is the type that is used for fertilizer application in agriculture, most commonly in prill/granule form. Transportation of AN with not more than 0.2% combustible substances (including any organic substance calculated as carbon, to the exclusion of any other added substance) is covered by 49 CFR § 172.101 with label code 5.1 Oxidizer, UN1942.

2.7.2 Storage of Ammonium Nitrate

Under the recommendations issued by the National Fire Protection Association (NFPA) Code for the Storage of Liquid and Solid Oxidizers [483], AN was ranked along with all other inorganic nitrates as a Class 1 oxidizer, which is the oxidizer class with the lowest hazard rating. As such, the requirements (number and spacing of

sprinklers, separation from nearest important structure, non-combustible materials of construction for storage buildings and storage bins) had to be met only for storing more than 1814 kg (4000 lb_m) of AN in one location. To anybody who remembers the extent of damage caused by the Texas City and Toulouse disasters, this seems to be a very lenient classification of the potential hazards of AN storage. In the most recent revision of NFPA 400, Hazardous Materials Code, the Technical Committee classified AN as a Class 2 oxidizer. The burning rate of technical-grade AN prill falls within the Class 2 oxidizer criteria in Annex G of NFPA 400 (2016) [484].

The Occupational Safety and Health Administration (OSHA) standard at 29 CFR 1910.109(i) contains requirements for AN stored in the form of crystals, flakes, grains, or prills [485].

2.7.3 Accident History of Ammonium Nitrate Explosions

The conditions under which the decomposition of AN can transition into a deflagration and then into a detonation were thoroughly investigated in the wake of several disasters, most prominently the explosion of two shiploads of AN in Texas City, Texas, on 16 April 1947. About 2500 tons of AN packed in paper bags were in the cargo hold of the vessel *SS Grandcamp* when it first smoldered and then exploded, killing more than 500 people and injuring 4000 more. A second explosion occurred 20 h later involving 900 tons of AN in the cargo hold of the *High Flyer*, which was moored next to the *Grandcamp*, but that explosion caused only one more fatality [486]. The news of the explosion at Texas City had barely spread around the world when a similar explosion aboard the *SS Ocean Liberty* shook the harbor of Brest, France, on 28 July 1947. In view of such destructive behavior, who would want to use AN as a rocket propellant?

Even in mixtures of AN with ammonium sulfate (AS), which is a fertilizer mixture, AN is still detonable, as an industrial accident in Oppau, Germany, in 1921 showed when people foolishly tried to loosen a chunk of caked AN/48.5% AS by setting off an explosive charge in a silo, which had been done several times before without any ill effects. The entire silo containing 4500 tons of the fertilizer exploded, killing 561 people, injuring 2000 people, flattening the chemical factory, and causing destruction for miles around [487–489]. The crater at the location of the former storage silo was 100 m in diameter and 19 m deep (Figure 28). Similar explosions have occurred at numerous other industrial installations (Table 27).

Process safety, as well as the safe storage and transportation of AN, has been a topic of increasing interest in the last few decades. The increased interest in improving the safety of AN operations has been driven largely by a series of explosion catastrophes that have occurred in the United States and the rest of the world. A review of past incidents and disasters to look for common causes and lessons to be learned is an

Figure 28: Aftermath of the explosion of an ammonium nitrate/ammonium sulfate mixture at Oppau, Germany, in 1921. (Photo courtesy of Stadtarchiv Ludwigshafen, Fotosammlung Nr. 23639)

essential component to any process safety and loss prevention program. Although analyzing the causes of an accident cannot prevent that accident from occurring, learning from it can help prevent future incidents. A review of major incidents involving AN in the last century was done to identify common causes and lessons that can be learned in the hope of preventing future disasters [490]. Ammonium nitrate has been involved in dozens of major incidents in the last century. Of those, 12 incidents were selected and reviewed, and lessons from these incidents have been shared with the rest of us. Although propellant manufacturing sites do not involve the same quantities of AN as in the fertilizer industry, the storage of raw ingredients nevertheless must meet all safety criteria, including setback requirements from the nearest occupied buildings and the property boundary.

At Terra Industries in Port Neal, Iowa, on 13 December 1994, an AN manufacturing unit exploded. Four employees were killed, and 18 were hospitalized. A total of 5700 tons of anhydrous ammonia and 25000 gallons of nitric acid were released. Resi-

Table 27: Summary of ammonium nitrate explosions.

Year	Location	Material involved	Consequences
1920	Stolberg, Germany	AN, all, induced by blasting	Civil explosion
1921	Kriewald, Silesia (now Knurow, Poland)	AN, all, induced by blasting, 25 t AN	19 dead, 23 injured
1921	Oppau, Germany	AN, all, induced by blasting, 4500/750 t AN + AS	561 dead, 1991 injured
1942	Tessenderlo, Belgium	150 t AN + AS, same as in Oppau	100 dead
1947	Texas City (× 2), Texas, USA	2300/962 t AN, fire → explosion	450 dead, 4000 injured
1947	Brest, France	3300 t AN, fire → explosion	21 dead
1953	Black Sea, USSR	4000 t AN, fire → explosion	
1964	Japan	2200 t AN, fire → explosion	
2001	Toulouse, France	300–400 t AN	31 dead, 200 injured
2013	West, Texas, USA	30 t AN	15 dead, 200 injured
2015	Tianjin, China	AN	165 dead, 798 injured, 8 missing
2020	Beirut, Lebanon	AN, fire → explosion	207 dead, 7500 injured

dents were evacuated from the surrounding area, and ammonia plumes were detected several miles away.

In West, Texas, on 17 April 2013, a chemical storage and distribution facility caught fire, followed by the explosion of around 30 tons of AN while the emergency responders were trying to extinguish the fire, leading to 15 fatalities and numerous buildings, businesses, and homes being destroyed or damaged. Authors of one publication investigated the root causes of the incident, presented a simplified consequence analysis, and discussed how the current regulations could be modified to prevent or minimize future losses [491]. See also [492–494].

2.8 Safety Properties of Ammonium Nitrate

For the sake of reproducibility and to be able to compare results obtained at different laboratories, safety properties of AN have been determined based on pure AN. However, that is not the grade of purity that is representative for the bulk of AN used in industry for propellants and explosives. Many of the real-life safety properties for industrial-grade AN may be quite different from what was measured in an academic laboratory using reagent-grade AN.

2.8.1 Explosive and Fire Hazards of Ammonium Nitrate

Until the Oppau disaster in Germany in 1921, AN was not considered an explosive in the absence of fuels. In the wake of this disaster, numerous investigations have been carried out to better characterize AN as an energetic material.

The likelihood of accidental explosions of AN is increased by the porosity created by repeated cycling though the 32°C IV ↔ III phase-transition temperature. The explosion sensitivity can be reduced by incorporating some potassium nitrate in the AN during crystallization (which also shifts unwanted phase changes) [495].

A study was directed toward determining conditions under which AN will explode when heated [496]: 2.26-kg (5-lb) charges of pure or fertilizer-grade AN were packed into bombs consisting of seamless steel tubes that were closed at one end and had vents measuring up to 19 mm (0.74 in) in diameter at the other. These bombs were wired for electric heating at rates up to about 1700 W. The fertilizer-grade AN came from the same suppliers that had supplied the ships in the Texas City disaster and had 0.7% of a wax coating and 3% clay as anticaking additive. Possible spontaneous heating of AN was investigated by placing about 20 thermocouples in the holds of a Liberty-type ship during the loading of some 8000 tons of AN fertilizer and making temperature records during the voyage, which occurred in the heat of summer between Louisiana and the Panama Canal Zone.

Deflagration-to-detonation transitions of molten AN can occur at any time, depending on the mode of confinement and the surface-to-volume ratio of the container [497, 498].

2.8.2 Drop-Weight Sensitivity of Ammonium Nitrate

Solid AN will explode in the drop-weight impact-sensitivity apparatus only at the upper limit of capability of most machines. Molten AN is much more sensitive and is easy to initiate by impact (Table 28). In the Picatinny Arsenal apparatus with a 2-kg weight, the 50% point was reported as 79 cm (31 in) for chemically pure AN and 74–81 cm (29–32 in) for AN coated with about 1% wax. For comparison, tests conducted

Table 28: Drop-weight impact sensitivity of ammonium nitrate at various temperatures.

Temperature		50% positive impact tests, inches			
K	°C	AN, chemically pure		AN, wax-coated	
298	25	78.7	31	76.2	30
373	100	68.6	27	55.9	22
423	150	68.6	27	58.4	23
448	175	30.5	12	30–32	12–13

Picatinny Arsenal apparatus, 2 kg weight
Data source: [499]

at the same time with Picatinny apparatus for standard explosives gave 43 cm (17 in) for Explosive D (ammonium picrate), 30.5–38 cm (12–15 in) for TNT, 20 cm (8 in) for tetryl, and 10 cm (4 in) for lead azide. In the U.S. Bureau of Mines apparatus with a 2-kg weight, no reaction was observed for chemically pure or wax-coated AN. The test at 448 K (175°C) showed that AN in the molten condition is much more sensitive than the solid material.

Mixtures of AN with metal powders are quite sensitive to shock. The shock sensitivity decreased in the order $\text{Ti} > \text{Sn} > \text{Al} > \text{Mg} > \text{Zn} > \text{Pb} > \text{Fe} > \text{Sb} > \text{Cu}$ [500]. For comparison, the autoignition temperature decreased in the order $\text{Zn} > \text{Mg} > \text{Pb} > \text{Fe} > \text{Cu} > \text{Ti} > \text{Sn} > \text{Sb} > \text{Al}$.

The sensitivity of AN can be modified by adding anti-explosion agents to reduce its impact sensitivity. Six different additives – ZnO , urea, Na_2HPO_4 , camphor, $\text{Mg}_2(\text{OH})_2\text{CO}_3$, and Na_2CO_3 – were mixed with AN and tested [501]. The impact-sensitivity test results of these mixtures at a drop height of 65 cm with a 10-kg drop hammer showed that in comparison with pure AN without additive, when 5% of a $\text{ZnO}/\text{Na}_2\text{HPO}_4/\text{Mg}_2(\text{OH})_2\text{CO}_3 = 33/34/33$ mixture was added to the system, the impact sensitivity could be decreased from 88 to 24% positive tests, and the impact sensitivity also declined with the decrease of hardness and density of modified AN.

Similar to what is observed with AP, the particle size of modified AN has a pronounced effect on its mechanical sensitivity [502].

In a round-robin test of AN drop-weight sensitivity performed by four different laboratories with the type 12 drop-weight sensitivity apparatus with a 2.5-kg weight, the average values for DH_{50} impact sensitivities were 156 cm for 120-grit sandpaper and 82 cm for 180-grit sandpaper [72]. One lab tested AN both dried and not dried using 180-grit sandpaper and found the material to be completely insensitive up to the limit of their equipment. Another lab using 180-grit sandpaper found the sensitivity to be much like what others had found for 120-grit sandpaper, with an average DH_{50} value of 201 ± 29 cm. A third lab tested a double-dried material and found the average DH_{50} value to be 60.5 ± 2.5 cm. The variations may be due to different relative humidities in the laboratory air. RDX and PETN were tested on the same equipment for comparison and calibration.

2.8.3 Cap Sensitivity of Ammonium Nitrate

Porous AN with uniform porosity of carefully controlled void fraction, average pore size, and pore size distribution can become cap sensitive, either as AN by itself [57, 503–505] or AN with fuel oil imbibed into the porosity. This material is often called “expanded ammonium nitrate.” This is similar to sensitizing liquid explosives by including microballoons. The collapse of voids under conditions of sudden adiabatic compression causes hot spots that aid the propagation of low-velocity detonation.

The bulk density of expanded AN is typically $0.35\text{--}0.6\text{ g/cm}^3$. At a density of 0.35 or 0.6 g/cm^3 , the material is no longer cap sensitive [506].

The sensitivity of commercial grades of AN can change after it leaves its manufacturing site and is exposed to various changes and multiple cycles of temperature and humidity during transport and storage, depending on the weather [507]. Contaminants can either catalyze or inhibit the detonability of AN [508].

2.8.4 Card-Gap Sensitivity of Ammonium Nitrate

The distances over which sympathetic detonation of AN and ANFO might be expected were measured in large-scale gap tests using two types of ANFO donor charges in three sizes with AN, both at ambient and elevated temperatures, and ANFO acceptor charges [509]. The up-and-down experimental design was chosen to determine the 50% initiation point. The acceptor charges were instrumented to indicate initiation and to determine detonation velocity. Required separation distances between donor and acceptor were found to be larger than anticipated, both for the AN and the ANFO. With ANFO acceptors and a 16-gauge steel-faced donor, one initiation (positive test) occurred at a separation of 636 in = 53 feet or nearly 16 charge diameters. With AN by itself, initiation occurred at 4–5.5 charge diameters.

Liquid molten AN at 453 K (180 °C) was less sensitive in the card-gap test, with 1.5-in charge diameter in steel pipe than hot prilled AN heated to just below the melting point [510]. In these tests, the pressure was ~20 kbars and the detonation velocity was ~2000 m/s. Additional tests were conducted with heavy and with light confinement and with charge diameters of 7, 10, 15, 20, and 30 cm (3, 4, 6, 8, and 12 in). In a series of tests with 4-in samples with light confinement and a 320-g tetryl booster with incrementally increased initial sample temperature, prilled AN started to become detonable at 398–413 K (125–140 °C). Because AN and urea are both used as fertilizer and are often mixed and stored together or alternately shipped in shared transportation and storage containers, the card-gap testing included mixtures of AN and urea. The card-gap sensitivity of a 20% urea/80% AN mixture was positive at 2.3 in, showing a narrow range of detonability and a sharp maximum when the go/no-go boundary was plotted in a card gap vs. composition diagram.

The conditions under which AN can be brought to a state of sustained detonation by incidental and explosive derived shocks were determined, especially under conditions of fire exposure [511, 512]. The results indicated that the shock sensitivity of molten AN increased exponentially from 493 to 533 K (220 to 260 °C), at which point the shock sensitivity approached that of nitroglycerine-based dynamites. Subsequently, critical parameters for low-amplitude shock initiation of molten AN and AN fertilizer solutions were determined in a series of experiments [513].

Ammonium nitrate has been modified with non-explosive additives to prevent its use in illegitimate, clandestine bomb making. The thermal stability of normal AN and anti-explosive additive-treated AN (AEAN) was examined using accelerating rate calorimetry, and apparent activation energy and pre-exponential factor were calculated. The cap sensitivity of ANFO made with normal AN and with AEAN was com-

pared in field tests. AEAN/FO did not detonate. The elimination of AEAN explosive characteristic was assumed to be due to the improvement of its thermal stability [379, 380].

2.8.5 Friction Sensitivity of Ammonium Nitrate

Pure AN by itself is not friction sensitive. In the BAM friction sensitivity tester, no reaction was detected at the upper limit load of the machine at up to 353 N pistil load.

The friction sensitivity of AN/fuel oil or AN/paraffin mixtures culminates at 0.75–1.5% hydrocarbon. This is below the stoichiometric ratio where one would expect maximum sensitivity. This has been explained by the hydrocarbon sensitizing the AN at low concentrations but lubricating the mixture at higher concentrations. AN/hydrocarbon mixtures are still much less sensitive than corresponding AP/hydrocarbon mixtures.

In a round-robin test of AN friction sensitivity performed by four different laboratories with the BAM friction apparatus, all participants found AN to be insensitive to friction at the maximum load of the machine (353 N = 37 kg_f) [72]. RDX and PETN were tested on the same equipment for comparison and calibration.

2.8.6 Electrostatic Discharge Sensitivity of Ammonium Nitrate

There was concern that AN dust formed during pulverizing, pouring, pneumatic feeding, or mixing of AN may carry electrostatic charges that might accumulate and cause accidental ignition. The electrostatic charge buildup of modified AN dust, based on a continuous mixing operation of modified AN explosive, was simulated, and the electrostatic charge in the pneumatic airflow transportation process was measured [514]. Experimental data indicated that although the gas–solid concentration and the discharge voltage were quite high, AN did not ignite. The results showed that the electrostatic spark sensitivity of modified AN was E_{50} 2074 mJ, and the minimum electrostatic ignition energy was 1104 mJ. It was concluded that the modified AN dust was resistant to electrostatic discharges in the pneumatic airflow transportation process.

In a round-robin test of AN electrostatic discharge sensitivity performed by four different laboratories with custom-built apparatus, 20 negatives out of 20 tests were achieved at 0.12–0.32 J, but incipient reaction occurred with discharges of 0.31–0.85 J [72].

2.8.7 Bullet-Impact Sensitivity of Ammonium Nitrate

Fertilizer storage adjacent to areas open for public hunting may be subject to unintended stray bullets. In other instances, fragments from one exploding AN container may hit an adjacent container in a case of fratricide. The projectile-impact sensitivity of AN was tested in a T-shaped test fixture holding 2 kg of AN where the projectile first had to penetrate a 1/8-in-thick aluminum front plate [510]. The results demon-

strated that AN, as hot prills or liquid, could be initiated to an apparent detonation by bullet impact if the bullet had sufficient velocity. In the temperature range of 373–413 K (100–140 °C), the prills were initiated, and it was possible to obtain 50% velocities under elevated temperature conditions. Projectile velocity was varied from 800 to 3500 m/s, and the velocities at which half of the tests resulted in explosions were 1000–1500 m/s. See also [515].

2.8.8 Cook-off and Bonfire Tests with Ammonium Nitrate

Several incidents have occurred in which AN that was involved in a fire exploded. The specific hazardous properties are determined by the physical properties (particle size, porosity, density), chemical properties (stabilizers, moisture), and environmental factors (confinement, contamination, temperature, and pressure) of AN [516]. Molten AN is somewhat unique among explosive compounds in that its density can be varied by either raising or lowering the temperature in the fluid, especially at temperatures higher than 483 K (210 °C). Confinement and/or contamination appear to be important parameters for causing an AN explosion by the action of heat alone.

In addition to studying the possibility of AN explosions initiated by simple burning, the initiation of detonation by shocks derived from nearby gas explosions or from projectile impact was investigated as a function of temperature and charge diameter [510]. The burning of raw or contaminated AN under pressure did not lead to explosions. No transition from burning to detonation was experienced in burning AN. The critical diameter for detonation of fertilizer-grade AN was quite small when the AN was preheated to temperatures just below its melting point. Transitions from burning to detonation were observed in AN intimately mixed with fuels such as polyethylene, paper, or fuel oil when these materials were contained in vessels with restricted vents. AN by itself was heated in 4-ft-diameter vessels with various orifice sizes ranging in diameter from 1/8 in to 3/4 in. In many cases the sample decomposed for 100–150 ms with little pressure increase, but then the rapid pressure increase would burst the vessel. It was concluded that the initiation of detonation in AN from fire exposure in normal storage and during transportation accidents is unlikely. A flashover explosion in an adjacent compartment where pyrolysis gases from pyrolyzed solid combustibles accumulate and then ignite and explode may be strong enough to initiate the hot AN. Because AN and urea are both used as fertilizer and are often stored together or alternately shipped and stored in shared containers, the bonfire testing included mixtures of AN and urea.

A modified vented pipe test was used to study the cook-off behavior of AN prills, AN suspensions in water, and AN emulsions, with the samples filled to three-quarters full in a steel container with an array of thermocouples and heated from below with a propane burner [517]. The apparatus would typically hold 28 kg AN. Pure AN decomposed without venting or explosion in the modified vented pipe test.

Self-sustaining decomposition (SSD) of AN and AN fertilizer blends is often a pre-stage to explosion. Based on the consequence analysis of SSD, early detection of decomposition in storage warehouses and proper temperature control in the manufacturing process is important [63]. SSD and oxidizing properties were found in AN/KN compositions where the K3 phase exists. It was assumed that potassium nitrate forms a solid matrix in which AN can decompose. A high bulk density is of key importance for detonation resistance.

Ammonium nitrate under fire exposure is a well-established explosion hazard and has been responsible for some of the greatest industrial accidents to date. The investigative literature on AN thermolysis is reviewed in [518]. Morphology, decomposition pathways, and the shock sensitivity of AN are influenced by elevated temperatures and heating rates. However, researchers have never been able to induce explosion in pure AN under controlled conditions by heat alone. Here, other factors play an important part. Of these, confinement stands out as a key determinant. Elevated pressure increases gas–solid-phase interactions under decomposition, promoting exothermic behavior, even for pure AN. This is an important feature to consider if bulk amounts of AN are subjected to fire. Due to the endothermic behavior of AN dissociation, however, AN is in most cases a relatively stable compound even when heated. Strictly defined conditions are necessary for achievement of deflagration-to-detonation transitions or just deflagration alone [497]. Heat exposure is the most obvious, generic, and critical cause of explosion in any fire-related AN explosion.

2.9 Explosive Performance of Ammonium Nitrate

Ever since the Texas City disaster in 1947, the detonability of AN by itself and of AN with various contaminants and additives has undergone thorough examination. For the rocket propellant chemist, the main concern is the accidental detonability of AN while it is being made, stored, shipped, or processed into rocket propellants, and a later concern is the bulk detonation properties of AN-based rocket propellants and gas generants in the field under various conditions of energetic stimuli. See also [519].

2.9.1 Detonation Velocity of Ammonium Nitrate Detonations

The detonation velocity of AN detonations is mostly of academic interest, but it also relates to the detonation velocity of AN-based blasting agents such as ANFO. There is no relationship between the detonation velocity of AN in explosives and the strand-burning velocity of AN in rocket propellants. Nevertheless, some of the information on detonation of AN is presented here because it may help to explain AN accidents.

A reactive force-field parametrization initially developed for nitramine/TATB explosives was optimized to reproduce electronic structure calculations for dissociation barriers, heats of formation, and crystal structure properties of AN phases [520]. With

this tool, the isothermal pressure-volume curve and the unreacted principal Hugoniot states of AN were predicted. The predicted isothermal pressure-volume curve for phase IV solid AN agreed with electronic structure calculations and experimental data within 10% for the considered range of compression. The predicted unreacted principal Hugoniot states were approximately 17% stiffer than experimental measurements. A simulated thermal decomposition during heating to 2500 K agreed with experimental findings.

2.9.2 Detonation Velocity of Ammonium Nitrate/Fuel-Mixture Detonations

There are hundreds of patents on ANFO-type explosives, which we do not include in our collection. We are interested only in AN/fuel mixtures that can potentially be used as rocket propellants. A mixture of AN with hydrocarbons (ANFO explosive) does not burn (slow strand burn) below at least 40 MPa, whereas addition of 4% charcoal results in a mixture capable of strand burning at 1.7 MPa. The effect of organic fuels (guanidinium nitrate, mannitol, sorbitol, PETN) on detonation parameters of AN mixtures has been measured [521].

2.9.3 Critical Density of Ammonium Nitrate Detonations

Explosives can be classified into two types: For compounds of the first type, which includes high explosives (TNT, RDX, and others), the detonation velocity (D) increases linearly with an increase in density (ρ). Explosives of the second type are characterized by **non**-monotonic dependence $D = f(\rho)$. The detonation velocity for those substances first increases with density and then passes through a maximum, and then detonation fails to propagate past a certain distance from the booster. These explosives of the second type are referred to as *non-ideal* explosives and include individual chemical compounds (AN, AP, ADN, nitroguanidine, and HN) and many explosive compositions of the oxidant/fuel type. The reasons for such a behavior of $D = f(\rho)$ for individual explosives and explosive compositions are different [522].

2.9.3.1 Critical Density of Ammonium Nitrate/Solid Fuel–Mixture Detonations

We are interested only in the accidental detonation behavior of AN-based rocket propellants and gas generants that were not supposed to be detonable as designed but that may become detonable if not properly formulated or if they are exposed to extreme stimuli or have deteriorated during aging. The detonability of mixtures of AN with liquid fuels (such as ANFO, which is for a different business) will be discussed but only in passing.

Ammonium nitrate in mixtures with urea makes a very good garden fertilizer. The effect of urea on the detonation characteristics of AN was investigated [327]. The thermal sensitivity and shock sensitivity of the samples were examined using the Koenen test and the UN gap test. It turned out that 50AN-50urea mixtures can still produce

a steady detonation in the UN gap test. Addition of less than 50% urea cannot reduce the ability of AN to propagate a detonation.

2.9.3.2 Critical Diameter of Ammonium Nitrate Detonations

The detonation of technical-grade AN at the density $\rho = 0.666 \text{ g/cm}^3$ confined in PVC and steel tubes was studied experimentally [523]. The results showed that the detonation is self-sustained and steady in steel tubes with diameters as small as 12 mm. Critical detonation diameter lies between 8 and 12 mm in 2-mm-thick steel tubes and between 55 and 81 mm in PVC tubes. These values are indicative of a strong detonation sensitivity of this product. The results are dependent on the packing density of the material. Figure 29 shows the critical diameter of unconfined prilled AN as a function of the packing density [524].

Figure 29: Critical diameter of unconfined AN as a function of packing density. (Reproduced and modified from [524].)

Critical Diameter of Ammonium Nitrate/Solid Fuel–Mixture Detonations

In order to obtain a better understanding of detonation properties of AN and activated carbon (AC) mixtures, a series of steel tube tests with several different diameters was carried out for various compositions of powdered AN and AC mixtures, and the influence of the charge diameter on the detonation velocity was investigated [525]. The test results indicated that the detonation velocity increased with the increase of the charge diameter (as expected). The experimentally observed values were far below the theoretically predicted values made by the thermohydrodynamic CHEETAH code, and they showed so-called non-ideal detonation. When extrapolating the detonation velocity of stoichiometric compositions to infinite diameter samples, the numbers showed good agreement with the theoretical values. Mixtures of AN with AC and

Al were extensively used as military and commercial explosives under the designation “ammonal.”

2.9.4 Explosive Yield of Ammonium Nitrate

The explosive yield of AN by itself is not very good. Most explosive applications will use mixtures of AN with combustible organics (fuel oil, wax, sawdust) to improve the explosive yield. The Trauzl lead block indentation of dry AN by itself can be as high as $180\text{ cm}^3/10\text{ g}$. Lead block indentation tests of commercial-grade AN fertilizer samples were conducted before and after normal and accelerated aging and temperature cycling [526].

A 10-g charge of AN in a Trauzl lead block can be detonated completely by a No. 8 blasting cap, but detonation was not complete with a No. 6 cap, and with smaller caps no detonation occurred. The Trauzl block cavity volume increase was about 165 cm^3 .

2.9.5 Velocity and Critical Diameter of Ammonium Nitrate Detonations

Detonation velocities ranged from 1200 to 1900 m/s when AN was loaded at density of $0.65\text{--}1.0\text{ g/cm}^3$ in wrought-iron tubes having diameters of 2.5–10 cm and the charges were detonated by means of boosters consisting of 50–300 g of tetryl or picric acid (PA). Detonations of AN were observed only when the charge diameter (“limit charge diameter”) was greater than 80–100 mm (Table 29). When heavy confinement casings, such as concrete, were used, or when explosions were under water, the limit charge diameter decreased to 30–40 mm [527].

Table 29: Detonation velocity of ammonium nitrate at room temperature.

Density g/cm ³	Charge diameter mm	Confinement	Initiation charge No. 8 cap plus:	Detonation velocity m/s
0.69	50	Steel tube	100 g PA	1230
0.84	25	Steel tube	50 g tetryl	1310
0.83	26	Steel tube	60 g tetryl	1470
0.79	80	Steel tube	100 g PA	1530
0.88	80	Steel tube	100 g PA	1550
0.84	100	Steel tube	200 g PA	1820
0.64	100	Steel tube	100 g PA	1920

Data source: [527, 528]

A later investigation [529] measured the detonation velocity of pure AN (as well as of its mixtures with TNT and with Composition B) as a function of charge diameter. A hand-tamped charge of AN in paper tubing with a diameter of 12.72 cm failed to detonate. Average rates in larger-diameter paper tubes were as listed in Table 30. In a different test,

rates of detonation of pure AN packed in steel tubes at an approximate packing density of 0.96 g/cm^3 were 2570 m/s in 12.7-cm (5-in)–inner-diameter (ID) tubes and 1681 m/s in 10-cm (4-in)–ID tubes, but there was failure to propagate in 7.5-cm (3-in)–ID tubes. The rate of detonation of AN increases with increasing diameter of the charge, and if the diameter is great enough, unconfined AN can detonate, but then the rate decreases with increased distance from the initiator and the process eventually “fizzles out.”

Table 30: Detonation velocity of ammonium nitrate in large-diameter charges.

Charge diameter cm	Detonation velocity m/s
16.0	1300
19.99	1500
25.4	1750
35.7	2150
40.4	2360
46.0	2760

Data source: [529]

It has been known for many years that AN, even when free from combustible material, can detonate. This is not surprising, since the products of decomposition must be entirely gaseous and have substantially less energy of formation than the original substance. For example, if the nitrogen is not oxidized, the energy released at constant volume, with water in the vapor phase, is 1590 J/g (380 cal/g) or 8.7 kcal per mol of gas. This is rather low compared with typical values for explosives, which lie in the range of $20\text{--}50 \text{ kcal/mol}$ gas. One might expect the substance to detonate with difficulty and only under good confinement. For normal AN at bulk densities around 1 g/cm^3 , cartridge diameters of many inches or heavy metal tubes are necessary to achieve detonation, and even then the measured speeds are much lower than the maximum values calculated for products $\text{N}_2 + 2\text{H}_2\text{O} + \frac{1}{2}\text{O}_2$. This has led some authors to conclude that an equilibrium involving oxides of nitrogen is more appropriate and that the release of energy is of the order of 962 J/g (230 cal/g) [530].

Detonation velocity and pressure of low-density prilled AN was measured in steel tubes of varying diameters and wall thicknesses [531]. Tube diameter had a much more pronounced effect on detonability than the confinement. The detonation velocity and pressure extrapolated to infinite diameter were 3.85 km/s and 3.2 GPa , respectively, which were in agreement with predicted ideal detonation parameters from the TIGER computer code.

2.10 Toxicity of Ammonium Nitrate

2.10.1 Oral Toxicity of Ammonium Nitrate

For most people, the highest probability of daily nitrate exposure is through its natural occurrence in vegetables, particularly beets, celery, lettuce, parsley, broccoli, carrots, radishes, rhubarb, spinach, melons, and turnip greens. These vegetables accumulate nitrates, including AN because of its natural occurrence and agricultural application as a fertilizer.

Another potential source of nitrate is drinking water. Drinking water coming from private wells, particularly in agricultural areas, can be contaminated with higher levels of nitrates, primarily from fertilizer runoff, animal manure, and human sewage from septic tanks. Tolerable nitrate levels are regulated in public water supplies. The U.S. Environmental Protection Agency has established a limit of 1 ppm for nitrite and 10 mg/L for nitrate. See also [532].

2.11 Ammonium Nitrate–Based Rocket Propellants

Formulations and processing of AN-based rocket propellants will be described in detail in planned future volumes of the *Encyclopedia of Rocket Propellants*. Here we only summarize the properties and applications of AN as an oxidizer.

One of the first summary publications on AN as a rocket propellant has now been declassified [533]. This is a real classic, but some of the problems with AN first recognized in 1954 persist to this date.

As of 1994, a commercial source for propulsion-grade AN (PROGRAN), a stabilized, controlled-particle-size AN suitable for the formulation of propellants and gas generants, was available at Nobel Explosives Co. in the United Kingdom [534].

Ammonium nitrate promises to be an environmentally-friendly oxidizer in gas generators and propellants. Ammonium perchlorate, which is the workhorse oxidizer in composite propellants, may need to be replaced because of its environmental and human health issues. In this context, AN is regarded as an alternative to AP because it is readily available and its combustion products are environmentally friendly and chlorine free. However, AN has its own inherent drawbacks, such as hygroscopicity, room-temperature phase transition, and low burning rate. Several aspects of polymorphism, phase stabilization, thermal decomposition, hygroscopicity, specific impulse, and burn-rate modification of AN have been reviewed, and ways to overcome the inherent weakness of AN as a propellant oxidizer to formulate more effective and less hazardous gas generant and propellant compositions were pointed out [535].

2.11.1 Ammonium Nitrate–Based Gas Generants

A continuing problem with all gas generant and propellant formulations based on AN is the prevention of AN phase changes. Incorporating AN into a binder matrix has very little effect on phase changes of AN and does not prevent them. Other additives, typically added to or co-crystallized with the AN before mixing it with a binder, are required to prevent swelling of the grains and delamination of the oxidizer–polymer bond as a result of temperature cycling. A substantial amount of experimental effort has gone into the development of AN-based gas generants for a variety of military and commercial applications. While the ready availability of AN and its low flame temperature make it attractive as a gas generant ingredient, the problems with unavoidable or only partially preventable phase changes have delayed their application.

2.11.2 Ammonium Nitrate–Based Explosives

Until the Oppau disaster in 1921, AN was not considered an explosive. Commercial AN-based explosives will contain a sensitizing agent (fuel, fuel oil, high explosive) to make it cap sensitive or at least booster sensitive as a blasting agent. Another method to sensitize AN is to make it highly porous (“self-sensitized”).

There are several thousand patents on AN-based explosives and blasting agents. Many of the patents are so similar to each other that one really wonders how they could wiggle their way through the patent office’s system without being rejected by the examiner or challenged by a competitor with earlier priority.

This book is about rocket propellants and not about explosives. In a few cases, explosives-derived know-how has come back to benefit propellant applications of AN, and that is why a few typical AN-based explosives and blasting agents are included here. The propellant formulator must know the limits between an energetic rocket propellant and an explosive. The propellant formulator must understand the explosive properties of AN/fuel mixtures before he or she can intelligently formulate an AN-based propellant. Propellant formulators often walk a fine line between making a good propellant and making a poor explosive. In some cases, the line may shift if large-scale energetic events are involved and the effect of the scale factor is forgotten. See also [536].

2.11.2.1 Porous Ammonium Nitrate–Based Explosives

Porous (“expanded”) AN can be made by rapid crystallization from supersaturated solutions (Section 2.2.3.2). Additional porosity is often added to AN-based blasting agents, slurries, and emulsions in the form of glass or plastic microballoons.

2.11.2.2 Ammonium Nitrate/Fuel Oil Explosives

There are hundreds of patents on ANFO-type explosives, which we do not include in our collection. We are interested only in AN/fuel mixtures that can potentially be used

as rocket propellants. A few studies on explosions of AN in mixtures with organics (mostly fuel oil) are included here because similar hazardous situations may occur during the mixing of AN-based propellants or gas generants in large-batch mixers. The test methods used to establish the safety of ANFO mixtures can also be used to measure the sensitivity of AN-based gas generants and propellants.

One report summarized results of tests on the sensitivity of various experimental explosive systems using AN as the oxidizing agent [537]. The sensitivity survey included drop-weight and friction testing and sensitivity to initiation by projectile impact and a No. 8 blasting cap. It was found that certain types of AN prills can result in cap-sensitive mixtures when combined with No. 2 diesel fuel (FO). Prilled AN mixed with nitromethane also resulted in cap-sensitive mixtures. Mixtures of prilled AN and neat 1-nitropropane and 2-nitropropane were not cap sensitive, and the use of powdered or grained aluminum in ANFO did not adversely affect the sensitivity, except possibly to increase its sensitivity to friction.

2.11.2.3 Ammonium Nitrate-Nitroalkane Explosives

Instead of using hydrocarbons with a high oxygen demand, explosives with a lower AN content can be formulated by replacing the alkanes with nitroalkanes, which bring some oxygen of their own and do not totally depend on AN as the oxidizer. Some of these nitroalkanes, such as nitromethane, may even be detonable on their own without the assistance of AN. AN/nitroalkane explosives may even be cap sensitive, thus eliminating the need for a booster charge in quarry-style or seismic exploration operations [538, 539]. The preferred mass ratio of AN to nitroethane is 80 : 20. A mixture containing 50.5% AN, 30% nitromethane, 10% H₂O, 5% urea, 2% microballoons, 2% nitrocellulose, and 0.5% guar gum had a detonation velocity of 5867 m/s in 3-in-diameter charges and 4663 m/s in 2-in-diameter charges. It did not crystallize at temperatures down to 285 K (12 °C), but it required a booster of at least 10 g of C-4 [540].

2.11.2.4 Ammonium Nitrate-Water-Gel Explosives

Another widely used category of AN-based explosives consists of those using AN mixtures with other alkali metal nitrates or alkaline earth-metal nitrates, with just enough water added to facilitate mixing and which are then emulsified with an organic fuel and stabilized by a gelling agent. Such liquid slurries can be easily pumped into boreholes at the blasting site and are relatively safe to handle. There are hundreds of patents on water-gel explosives and slurry explosives containing AN as the main ingredient.

2.11.2.5 Eutectic Ammonium Nitrate Explosives

The objective of developing eutectic AN melt-cast explosives was to find economical replacements for TNT in bomb fill and large-scale demolition tasks. Some of the eutectics developed for explosive applications are also of interest as solid propellants.

Although eutectics do not segregate during cooling, they do not totally avoid the troublesome expansion of AN as a result of temperature cycling.

Failure diameter and impact, thermal, and shock sensitivities for eutectic mixtures of AN with various additives have been measured [541, 542]. Compatibility of the eutectics with nitroguanidine (NQ) was unusually good, as shown by very little gas evolution with storage at elevated temperatures. Performance of mixtures of AN/ammonium 3,5-dinitro-1,2,4-triazolate (ADNT) with NQ, aluminum (Al), or EDDN/KN has been determined. Measurement of the irreversible growth of pressed pellets in which 15% of the AN was replaced by KN during temperature cycling showed that some grains swelled by 11 vol-% after temperature cycling.

2.11.2.6 Ammonium Nitrate/Metal Explosives

Any combustible metal will add sufficient energy to the AN decomposition reaction to make the mixtures detonable. For industrial applications, the preferred metal would be aluminum in the form of a fine powder.

Pure AN is not treated as an explosive compound, but a slight addition of organic or inorganic combustibles makes the mixtures capable of explosion. Experimental detonation tests focused on aluminum as the most effective sensitizer. Mixtures of AN or aqueous solutions or slurries of AN with aluminum (ammonals and hydro-ammonals) were studied using an electromagnetic method of measuring the mass velocity behind the detonation wave front, detonation parameters, and the shape of detonation waves in explosive mixtures [543].

2.11.3 Gas Generator Applications Based on Decomposition of Pure Ammonium Nitrate

A gas generator has been patented that consists of a solid grain of AN containing only insufficient binder or catalyst to sustain self-decomposition [544]. Decomposition in a pressurized chamber is initiated and controlled by a movable catalyst (a nichrome metal grid impregnated with a potassium dichromate catalyst) on a control rod that can be moved in and out of the proximity of the AN grain. The catalyst would be preheated by an electric heater to get the reaction started, or it might still be hot from a previous operation. This device can be restarted repeatedly, and the gas output can be controlled similarly to moving boron rods in and out of a nuclear reactor. The oxidizer-rich off-gas is kept at a temperature near 673 K (400 °C) to prevent condensation and then is fed to a bipropellant rocket engine, where it is combusted with a solid, liquid, or gaseous fuel (preferably a fuel hypergolic with the hot oxidizer-rich gas) to produce thrust. Lithium hydride in polyethylene would be one hypergolic fuel option. The device can be used for an astronaut hand-held maneuvering unit.

2.12 Ammonium Nitrite

Ammonium nitrite, NH_4NO_2 , CAS RN 13446-48-5, is the less oxygen-rich relative of AN, but it is much more reactive than AN. Ammonium nitrite occurs naturally in large quantities, but only in small concentrations, wherever ammonia-oxidizing bacteria are at work. Small quantities of ammonium nitrite may occur as contaminants in AN and adversely influence its thermal stability. Ammonium nitrite is not an oxidizer to use but rather an oxidizer to avoid in rocket propellants. The tolerable amount of ammonium nitrite in AN for propellant and explosive applications is limited by military specifications. Ammonium nitrite may also be an intermediate in the thermal decomposition of AN. For this reason, some information on ammonium nitrite is included in this book.

2.12.1 Physical Properties of Ammonium Nitrite

Nitrous acid (HONO) exists in *cis* and *trans* isomer modifications, and ammonium salts of the two acids have different properties, in particular different IR spectra [545].

The heat capacity of ammonium nitrite was measured between 13 and 310 K with an adiabatic calorimeter [546]. Two phase transitions were found at 181.3 and 276.5 K. The heat of formation of ammonium nitrite is -272 kJ/mol (-65 kcal/mol). The density of ammonium nitrite is 1.69 g/cm^3 .

2.12.2 Chemical Properties of Ammonium Nitrite

Ammonia is a weak base, and nitrous acid is a weak acid. The salt formed from the two compounds dissociates readily. Ammonium nitrite is highly unstable, both in a dry state and in concentrated aqueous solutions. When such solutions are used industrially for production of caprolactam, they are normally stored at a pH of 8–9 and a temperature of 278 K (5°C) or less. Ammonium nitrite decomposes in solution in the presence of acid or catalytic transition metal (e.g., chromium) ions. The military specifications for AN do not allow any detectable amount of ammonium nitrite in AN that is intended for use in explosives or propellants.

2.12.2.1 Thermal Decomposition of Ammonium Nitrite

A 0.25-g sample of NH_4NO_2 was decomposed completely after 2 min at 358–363 K ($85\text{--}90^\circ\text{C}$) or 9 min at 328–333 K ($55\text{--}60^\circ\text{C}$). Another sample of NH_4NO_2 was decomposed to 10% at room temperature after 6 weeks. Similar decomposition behavior is observed with hydrazinium nitrite and hydroxylammonium nitrite [547]. Ammonium dinitramide is substantially more stable than ammonium nitrite [548, 549].

2.12.2.2 Strand Burning of Ammonium Nitrite

Pressed samples of ammonium nitrite of 7-mm diameter are capable of burning even at subatmospheric pressure near 0.55 atm, while uncatalyzed AN will not burn at all at

atmospheric pressure [550, 551]. Similar to the relationship of the burning rates of ammonium chlorate and perchlorate, ammonium nitrite burns faster than AN containing a combustion catalyst (Figure 30).

Figure 30: Comparison of strand-burning rates of ammonium nitrite and ammonium nitrate. (Reproduced and modified from [551]; Cent. Eur. J. Energ. Mater.; licensed under Creative Commons <https://creativecommons.org/licenses/by-nc-nd/4.0/>.)

The strand-burning rate of NH_4NO_2 can be described by a straight line with two breaks: $r_b = 5.97p^{1.05}$ at pressure 0.1–4 MPa, $r_b = 13.62p^{0.44}$ at 4–20 MPa, and $r_b = 2.57p^{1.01}$ at 20–40 MPa. The thermal stability of ammonium nitrite is less than that of AN. Its autoignition temperature is 362–363 K (89–90 °C). If one plots experimental points of the burning rate vs. the initial temperature at atmospheric pressure, the results match those predicted for a condensed-phase reaction and not those for a gas-phase reaction. The surface temperature (dissociation temperature) of burning NH_4NO_2 at atmospheric pressure is 440 K (167 °C), which is significantly less than the surface temperature of burning AN (580 K). The decomposition rate of NH_4NO_2 is almost five orders of magnitude higher than the rate of the rate-determining reaction of NH_4NO_3 combustion.

2.12.3 Handling-Safety Properties of Ammonium Nitrite

There are no industrial uses for ammonium nitrite. Only a few laboratories have ever had to prepare this substance for scientific studies. Solid ammonium nitrite is an explosive substance, and its preparation should be attempted only in properly equipped laboratories. It is sensitive to mechanical shock, friction, and rapid heating. The hazard properties and the critical diameter for propagation of detonations have been determined [552, 553].

The effect of traces of chromium compounds on the decomposition of ammonium nitrite solutions was studied under isothermic and non-isothermic conditions [554, 555]. It was found that such compounds catalyze the decomposition of ammonium nitrite more intensely than HCl. This led to the conclusion that contamination by even small amounts of such contaminants should be carefully avoided in industrial work with ammonium nitrite solutions in order to minimize the danger of explosive decomposition.

3 Metal Nitrates

3.1 Alkali Metal Nitrates

Although potassium nitrate is the oldest rocket propellant oxidizer, dating back almost a millennium to the early Chinese experiments with black powder, very little is written now about this chemical. There is ample information about potassium nitrate and the other alkali metal nitrates in other readily available sources, including handbooks, websites, and encyclopedias, so we can cut our discussion of this oxidizer

Table 31: Physical properties of alkali metal nitrates.

Compound name	Formula	Molecular mass g/mol	Total oxygen content, mass-% O	Available oxygen, mass-% O	Melting point		Density at °C g/cm ³	Enthalpy of formation	
			mass-% O	mass-% O	K	°C		kJ/mol	kcal/mol
Lithium nitrate	LiNO ₃	68.94	69.62	58.02	525	252	2.38 (25°)	-482.4	-115.3
Sodium nitrate	NaNO ₃	84.99	56.47	47.06	585	312	2.257	-424.7	-101.5
Potassium nitrate	KNO ₃	101.10	47.47	39.56	607	334	2.109 (16.0°)	-492.5	-117.7
For comparison:									
Ammonium nitrate	NH ₄ NO ₃	80.04	59.97	19.99	442.7	169.6	1.725 (25°)	-367.9 -365.6	-87.93

short. Potassium nitrate is used as a stabilizer for AN and is used in igniter mixtures, the most frequently used being potassium nitrate and boron with a shellac binder. Potassium nitrate and black powder are used in many display and safe-and-sane fireworks articles. The physical properties of alkali metal nitrates are summarized in Table 31. A few other nitrates are listed for comparison.

3.2 Alkaline Earth-Metal Nitrates

The physical properties of alkaline earth-metal nitrates are summarized in Table 32. A few other nitrates are listed for comparison. Most of these metal nitrates crystallize with two, four, or six molecules of water in the sphere of hydration, but for their use in pyrotechnic formulations they have to be used in the anhydrous state. In the anhydrous state, the salts are quite hygroscopic. Most alkaline earth-metal nitrates begin to decompose when heated, even before they melt.

Table 32: Physical properties of alkaline earth-metal nitrates.

Compound name	Formula	Molecular mass	Total oxygen content,	Available oxygen,	Melting point		Density at °C	Enthalpy of formation	
		g/mol	mass-% O	mass-% O					
Mag- nesium nitrate	Mg(NO ₃) ₂	148.32	64.72	54.0	—	—	—	−791	−188.97
Calcium nitrate	Ca(NO ₃) ₂	164.088	58.50	48.8	834	561	2.504	−938	−224.28
Stron- tium nitrate	Sr(NO ₃) ₂	211.63	45.36	37.9	843	570	2.986	−978	−233.8
Barium nitrate	Ba(NO ₃) ₂	261.337	36.73	30.7	865	592	3.24	−768	−183.6
